Foreword

Welcome to the 19th edition of the International Conference of Extending Database Technology (EDBT). Originally biennial, the EDBT conference has been held annually and jointly with ICDT (“International Conference on Database Theory”) since 2009. This year, EDBT is taking place in Bordeaux, France, on March 15–18, 2016, continuing its long tradition as a top venue for presenting and discussing recent advancements in data management.

This year we received 137 submissions to the research track, 18 submissions to the vision track, 24 submissions to the industrial/application track, 28 submissions to the demo track and 11 tutorial proposals. The high quality of these submissions made the job of selecting the best of them rather challenging. The various program committees after thorough reviewing and careful consideration selected 38 research papers, 5 vision papers, 9 industrial/application papers, 16 demos and 3 tutorials. The proceedings include these contributions. A new addition this year is the poster track for presenting novel ongoing work. There were 64 submissions from which the poster program committee selected 31 contributions included in this proceedings.

The proceedings also include an overview of the keynote talk by Elisa Bertino (Purdue), an overview of the keynote talk by Gustavo Alonso (ETHZ) and a laudation concerning the EDBT 2016 Test of Time Award that was given to the paper

“Bridging Physical and Virtual Worlds: Complex Event Processing for RFID Data Streams” by
Fusheng Wang, Shaorong Liu, Peiya Liu, Yijian Bai, published in the EDBT 2006 proceedings.

The EDBT 2016 program is the result of the joint effort of many people that I would like to take this opportunity to thank. Ioana Manolescu (Vision Track Chair), Georgia Koutrika (Industrial/Application Track Chair), Letizia Tanca (Demo Track Chair) and Amelie Marian (Tutorial Chair), all did an excellent job, as Themis Palpanas with the workshops (whose proceedings appear in a companion volume). Thanks also to the members of the program committees of the various tracks that worked very hard to review each submission in detail and engaged in many discussions to create the best possible program.

Special mention should be made to the Test of Time Award committee members: Sihem Amer-Yahia, Yannis Ioannidis and Christian S. Jensen. The general chair, Sofian Maabout and the local organizers worked hard with all arrangements necessary for securing a successful event. Special thanks to Kostas Stefanidis, the proceedings chair, and Patrick Mary, the website chair, for their invaluable contribution to this event. Christine Collet and Norman Paton were instrumental in advising and coordinating with the EDBT Executive Board.

And lastly and most importantly, thanks to all the authors that submitted their work to EDBT 2016. Their contributions were what made this a strong program. I hope that you find the EDBT 2016 conference informative, enjoyable and thought-provoking!

Evaggelia Pitoura
EDBT 2016 Program Chair

Test-of-Time Award

In 2014, EDBT began awarding the EDBT Test-of-Time (ToT) Award, with the goal of recognizing one paper, or a small number of papers, presented at EDBT earlier and that have best met the “test of time”, i.e., that has had the most impact in terms of research, methodology, conceptual contribution, or transfer to practice over the past decade(s). The EDBT ToT Award for 2016 will be presented during the EDBT/ICDT 2016 Joint Conference, March 15–18, 2016, in Bordeaux (France). The EDBT 2016 Test-of-Time Award committee was formed by Sihem Amer-Yahia (CNRS, Laboratoire d’Informatique de Grenoble, France), Yannis Ioannidis (University of Athens, Greece), Christian S. Jensen (Aalborg University, Denmark), and all PC chairs of former EDBT conferences including EDBT 2006.

The committee was asked to select a paper or a small number of papers from the EDBT 2006 (Munich) proceedings. After careful consideration, the committee and the EDBT Executive Board have decided to select the following paper as the EDBT ToT Award winner for 2016:

**Bridging Physical and Virtual Worlds:
Complex Event Processing for RFID Data Streams**

by Fusheng Wang, Shaorong Liu, Peiya Liu, Yijian Bai

published in the EDBT 2006 proceedings, 588–607

The paper proposes an event-oriented approach to the processing of RFID data which makes it possible to automate the translation of RFID based application semantics through complex event detection. In particular, it demonstrates the ability to process complex events by capturing temporal constraints in an algebra. The resulting declarative event-based approach is shown to simplify RFID data processing and is shown to be scalable. The paper pioneers declarative event-based RFID processing. The simplicity and expressiveness of the proposed framework are admirable. For example, the framework makes it possible to express object tracking on historical data as well as to formulate real-time monitoring.

The committee and the EDBT Executive Board find that this paper stands out in terms of relevance, impact, and influence in databases. It has had substantial impact. In particular, it has impacted real systems, and the engine it proposes has been integrated into Siemens RFID Middleware. It is also the most cited EDBT 2006 paper, has spurred a significant amount of follow-up work, and remains relevant today.

Table of Contents

Foreword	i
Program Committee Members	ii
Test-of-Time Award	iv
Table of Contents	v
Invited Keynotes	1
Data Security and Privacy in the IoT <i>Elisa Bertino</i>	1
Data Processing in Modern Hardware <i>Gustavo Alonso</i>	4
Research Papers	5
Finding Users of Interest in Micro-blogging Systems <i>Camelia Constantin, Ryadh Dahimene, Quentin Grossetti, Cedric Du Mouza</i>	5
Slowing the Firehose: Multi-Dimensional Diversity on Social Post Streams <i>Shiwen Cheng, Marek Chrobak, Vagelis Hristidis</i>	17
Social, Structured and Semantic Search <i>Raphaël Bonaque, Bogdan Cautis, François Goasdoué, Ioana Manolescu</i>	29
Indexing Query Graphs to Speedup Graph Query Processing <i>Jing Wang, Nikos Ntarmos, Peter Triantafillou</i>	41
GSCALER: Synthetically Scaling A Given Graph <i>J.W. Zhang, Y.C. Tay</i>	53
Storing and Analyzing Historical Graph Data at Scale <i>Udayan Khurana, Amol Deshpande</i>	65
Providing Serializability for Pregel-like Graph Processing Systems <i>Minyang Han, Khuzaima Daudjee</i>	77
DBExplorer: Exploratory Search in Databases <i>Manish Singh, Michael Cafarella, Hosagrahar Visvesvar Jagadish</i>	89
Refinement Driven Processing of Aggregation Constrained Queries <i>Manasi Vartak, Venkatesh Raghavan, Elke Rundensteiner, Samuel Madden</i>	101
Reverse Engineering Top-k Database Queries with PALEO <i>Kiril Panev, Sebastian Michel</i>	113
CrowdSky: Skyline Computation with Crowdsourcing <i>Jongwuk Lee, Dongwon Lee, Sang-Wook Kim</i>	125
Cohesive Keyword Search on Tree Data <i>Aggeliki Dimitriou, Ananya Dass, Dimitri Theodoratos, Yannis Vassiliou</i>	137
Generic Keyword Search over XML Data <i>Manoj Agarwal, Krithi Ramamritham, Prashant Agarwal</i>	149
Answering Keyword Queries involving Aggregates and GROUPBY on Relational Databases <i>Zhong Zeng, Mong Li Lee, Tok Wang Ling</i>	161

Finding All Maximal Cliques in Very Large Social Networks <i>Alessio Conte, Roberto De Virgilio, Antonio Maccioni, Maurizio Patrignani, Riccardo Torlone</i>	173
RPM: Representative Pattern Mining for Efficient Time Series Classification <i>Xing Wang, Jessica Lin, Pavel Senin, Tim Oates, Sunil Gandhi, Arnold Boedihardjo, Crystal Chen, Susan Frankenstein</i>	185
Interactive Temporal Association Analytics <i>Xiao Qin, Ramoza Ahsan, Xika Lin, Elke Rundensteiner, Matthew Ward</i>	197
Efficient Record Linkage Using a Compact Hamming Space <i>Dimitrios Karapiperis, Dinusha Vatsalan, Vassilios Verykios, Peter Christen</i>	209
Scaling Entity Resolution to Large, Heterogeneous Data with Enhanced Meta-blocking <i>George Papadakis, George Papastefanatos, Themis Palpanas, Manolis Koubarakis</i>	221
Practical Query Answering in Data Exchange Under Inconsistency-Tolerant Semantics <i>Balder ten Cate, Richard Halpert, Phokion Kolaitis</i>	233
Querying RDF Data Using A Multigraph-based Approach <i>Vijay Ingalalli, Dino Ienco, Pascal Poncelet, Serena Villata</i>	245
Optimization of Complex SPARQL Analytical Queries <i>Padmashree Ravindra, HyeongSik Kim, Kemafor Anyanwu</i>	257
RDF-TX: A Fast, User-Friendly System for Querying the History of RDF Knowledge Bases <i>Shi Gao, Jiaqi Gu, Carlo Zaniolo</i>	269
Efficient Computation of Containment and Complementarity in RDF Data Cubes <i>Marios Meimaris, George Papastefanatos, Panos Vassiliadis, Ioannis Anagnostopoulos</i>	281
Semi-automatic support for evolving functional dependencies <i>Mirjana Mazuran, Elisa Quintarelli, Letizia Tanca, Stefania Ugolini</i>	293
Holistic Data Profiling: Simultaneous Discovery of Various Metadata <i>Jens Ehrlich, Mandy Roick, Lukas Schulze, Jakob Zwiener, Thorsten Papenbrock, Felix Naumann</i>	305
Monitoring MaxRS in Spatial Data Streams <i>Daichi Amagata, Takahiro Hara</i>	317
Similarity Search on Spatio-Textual Point Sets <i>Christodoulos Efstathiades, Alexandros Belesiotis, Dimitrios Skoutas, Dieter Pfoser</i>	329
Nearest Window Cluster Queries <i>Chen-Che Huang, Jiun-Long Huang, Tsung-Ching Liang, Jun-Zhe Wang, Wen-Yuah Shih, Wang-Chien Lee</i>	341
Adaptive query parallelization in multi-core column stores <i>Mrunal Gawade, Martin Kersten</i>	353
PARAGON: Parallel Architecture-Aware Graph Partition Refinement Algorithm <i>Angen Zheng, Alexandros Labrinidis, Patrick Pisciuneri, Panos Chrysanthis, Peyman Givi</i>	365
Query Workload-based RDF Graph Fragmentation and Allocation <i>Peng Peng, Lei Zou, Lei Chen, Dongyan Zhao</i>	377
Efficient Query Processing using the Earth's Mover Distance in Video Databases <i>Merih Seran Uysal, Christian Beecks, Daniel Sabinasz, Jochen Schmuecking, Thomas Seidl</i>	389
Probabilistic Threshold Indexing for Uncertain Strings <i>Sudip Biswas, Manish Patil, Sharma Thankachan, Rahul Shah</i>	401

Context-Aware Event Stream Analytics <i>Olga Poppe, Chuan Lei, Elke Rundensteiner, Dan Dougherty</i>	413
Who Cares about Others' Privacy: Personalized Anonymization of Moving Object Trajectories <i>Despina Kopanaki, Vasilis Theodossopoulos, Nikos Pelekis, Ioannis Kopanakis, Yannis Theodoridis . . .</i>	425
Identifying and Describing Streets of Interest <i>Dimitrios Skoutas, Dimitris Sacharidis, Kostas Stamatoukos,</i>	437
Finding Frequently Visited Indoor POIs Using Symbolic Indoor Tracking Data <i>Hua Lu, Chenjuan Guo, Bin Yang, Christian Jensen</i>	449
Visionary Papers	461
Designing Access Methods: The RUM Conjecture <i>Manos Athanassoulis, Michael Kester, Lukas Maas, Radu Stoica, Stratos Idreos, Anastasia Ailamaki, Mark Callaghan</i>	461
Self-Curating Databases <i>Mohammad Sadoghi, Kavitha Srinivas, Oktie Hassanzadeh, Yuan-Chi Chang, Mustafa Canim, Achille Fokoue, Yishai Feldman</i>	467
Data Wrangling for Big Data: Challenges and Opportunities <i>Tim Furge, Georg Gottlob, Leonid Libkin, Giorgio Orsi, Norman Paton</i>	473
Road to Freedom in Big Data Analytics <i>Divy Agrawal, Sanjay Chawla, Ahmed Elmagarmid, Zoi Kaoudi, Mourad Ouzzani, Paolo Papotti, Jorge Quiane, Nan Tang, Mohammed Zaki</i>	479
Data Management for Next Generation Genomic Computing <i>Stefano Ceri, Abdulrahman Kaitoua, Marco Masseroli, Pietro Pinoli, Francesco Venco</i>	485
Industrial and Applications Papers	491
Exploring Text Classification for Messy Data: An Industry Use Case for Domain-Specific Analytics <i>Laura Kassner, Bernhard Mitschang</i>	491
Discovering Correlations in Annotated Databases <i>Xuebin He, Stephen Donohue, Mohamed Eltabakh</i>	503
Query Performance Problem Determination with Knowledge Base in Semantic Web System OptImatch <i>Guilherme Damasio, Piotr Mierzejewski, Jaroslaw Szlichta, Calisto Zuzarte</i>	515
Scalable Public Transportation Queries on the Database <i>Alexandros Efentakis</i>	527
Characterizing Home Device Usage From Wireless Traffic Time Series <i>Katsiaryna Mirylenka, Vassilis Christophides, Themis Palpanas, Ioannis Pefkianakis, Martin May . . .</i>	539
Parallel Duplicate Detection in Adverse Drug Reaction Databases with Spark <i>Chen Wang, Sarvnaz Karimi</i>	551
e#: Sharper Expertise Detection from Microblogs <i>Thibault Sellam, Martin Hentschel, Vasilis Kandylas, Omar Alonso</i>	563
DECT: Distributed Evolving Context Tree for Mining Web Behavior Evolution <i>Xiaokui Shu, Nikolay Laptev, Danfeng Yao</i>	573
Strudel: A Framework for Transaction Performance Analyses on SQL/NoSQL Systems <i>Junichi Tatemura, Oliver Po, Zheng Li, Hakan Hacigumus</i>	580

Demonstrations	592
GROM: a General Rewriter of Semantic Mappings <i>Giansalvatore Mecca, Guillem Rull, Donatello Santoro, Ernest Teniente</i>	592
PowerQ: An Interactive Keyword Search Engine for Aggregate Queries on Relational Databases <i>Zhong Zeng, Mong Li Lee, Tok Wang Ling</i>	596
Visualization Through Inductive Aggregation <i>Parke Godfrey, Jarek Gryz, Piotr Lasek, Nasim Razavi</i>	600
Contextual Event Search: Finding Contextual Messages in Dynamic microblog Data Stream in Real Time <i>Manoj Agarwal, Divyam Bansal, Mridul Garg, Krithi Ramamritham</i>	604
Answering Controlled Natural Language Questions on RDF Knowledge Bases <i>Giuseppe Mazzeo, Carlo Zaniolo</i>	608
tPredictor: A Micro-blog Based System for Teenagers' Stress Prediction <i>Jing Huang, Qi Li, Zhuonan Feng, Yiping Li, Ling Feng</i>	612
OSNI: Searching for Needles in a Haystack of Social Network Data <i>Shiwen Cheng, James Fang, Vagelis Hristidis, Harsha Madhyastha, Niluthpol Chowdhury Mithun, Dorian Perkins, Amit Roy-Chowdhury, Moloud Shahbazi, Vassilis Tsotras</i>	616
PROX: Approximated Summarization of Data Provenance <i>Eleanor Ainy, Pierre Bourhis, Susan Davidson, Daniel Deutch, Tova Milo</i>	620
PAW: A Platform for Analytics Workflows <i>Maxim Filatov, Verena Kantere</i>	624
streamLoader: An Event-Driven ETL System for the On-line Processing of Heterogeneous Sensor Data <i>Marco Mesiti, Luca Ferrari, Stefano Valtolina, Giacomo Licari, Gianluca Galliani, Minh-San Dao, Koji Zettsu</i>	628
TINTIN: a Tool for INcremental INtegrity checking of Assertions in SQL Server <i>Xavier Oriol, Ernest Teniente, Guillem Rull</i>	632
Efficient regular path query evaluation using path indexes <i>George Fletcher, Jeroen Peters, Alexandra Poulouvassilis</i>	636
Galaxy: A Platform for Explorative Analysis of Open Data Sources <i>Seyed-Mehdi-Reza Beheshti, Boualem Benatallah, Hamid Reza Motahari Nezhad,</i>	640
OAPT: A Tool for Ontology Analysis and Partitioning <i>Alsayed Algergawy, Samira Babalou, Friederike Klan, Birgitta König-Ries</i>	644
ShapeExplorer: Querying and Exploring Shapes using Visual Knowledge <i>Tong Ge, Yafang Wang, Gerard de Melo, Zengguang Hao, Andrei Sharf, Baoquan Chen</i>	648
Distributed Secure Search in the Personal Cloud <i>Thu Le, Nicolas Anceaix, Sebastien Guilloton, Saliha Lallali, Philippe Pucheral, Iulian Sandu Popa, Chao Chen</i>	652
Poster Papers	656
Type-aware Web-search <i>Michael Gubanov, Anna Pyayt</i>	656
Indexing and Querying A Large Database of Typed Intervals <i>Jianqiu Xu, Hua Lu, Bin Yao</i>	658
Quantifying Likelihood of Change through Update Propagation across Top-k Rankings <i>Evica Milchevski, Sebastian Michel</i>	660

Optimizing B+-Tree for PCM-Based Hybrid Memory <i>Lu Li, Peiquan Jin, Chengcheng Yang, Zhanglin Wu, Lihua Yue</i>	662
A Data Mining Approach to Choosing Categorical Attributes for Ranked Lists <i>Koninika Pal, Sebastian Michel</i>	664
Efficient Implementation of Joins over Cassandra DBs <i>Haridimos Kondylakis, Antonis Fountouris, Dimitris Plexousakis</i>	666
Double Chain-Star: an RDF indexing scheme for fast processing of SPARQL joins <i>Marios Meimaris, George Papastefanatos</i>	668
Minoan ER: Progressive Entity Resolution in the Web of Data <i>Vasilis Efthymiou, Kostas Stefanidis, Vassilis Christophides</i>	670
Proposal of a Database Type and Aggregation Function for Accelerating Medical Genomics Study on RDBMS <i>Yoshifumi Ujibashi, Motoyuki Kawaba, Lilian Harada</i>	672
The Best Bang for Your Bu(ck)g <i>Benjamin Dietrich, Tobias Müller, Torsten Grust</i>	674
A Way to Automatically Enrich Biomedical Ontologies <i>Juan Antonio Lossio-Ventura, Mathieu Roche, Clement Jonquet, Maguelonne Teisseire</i>	676
A Distributed Mining Framework for Influence in Evolving Entities <i>Tian Guo, Karl Aberer</i>	678
Sweet KIWI: Statistics-Driven OLAP Acceleration using Query Column Sets <i>Sung-Soo Kim, Taewhi Lee, Moonyoung Chung, Jongho Won</i>	680
On-Line Mobility Pattern Discovering using Trajectory Data <i>Ticiana Coelho da Silva, Karine Zeitouni, José Fernandes de Macêdo, Marco Casanova</i>	682
Summarizing Linked Data RDF Graphs Using Approximate Graph Pattern Mining <i>Mussab Zneika, Claudio Lucchese, Dan Vodislav, Dimitris Kotzinos</i>	684
Understanding Customer Attrition at an Individual Level: a New Model in Grocery Retail Context <i>Clément Gautrais, Peggy Cellier, Thomas Guyet, René Quiniou, Alexandre Termier</i>	686
Towards an Efficient Ranking of Interval-Based Patterns <i>Marwan Hassani, Yifeng Lu, Thomas Seidl</i>	688

Data Security and Privacy in the IoT

Elisa Bertino
Department of Computer Science
Purdue University
West Lafayette, IN 47907
bertino@purdue.edu

ABSTRACT

Deploying existing data security solutions to the Internet of Things (IoT) is not straightforward because of device heterogeneity, highly dynamic and possibly unprotected environments, and large scale. In this paper, after outlining key challenges in data security and privacy, we summarize research directions for securing IoT data, including efficient and scalable encryption protocols, software protection techniques for small devices, and fine-grained data packet loss analysis for sensor networks.

1. INTRODUCTION

The Internet of Things (IoT) paradigm refers to the network of physical objects or “things” embedded with electronics, software, sensors, and connectivity to enable objects to exchange data with servers, centralized systems, and/or other connected devices based on a variety of communication infrastructures. IoT makes it possible to sense and control objects creating opportunities for more direct integration between the physical world and computer-based systems. When IoT is augmented with sensors and actuators, IoT is able to support cyber-physical applications by which networked objects can impact the physical environment by taking “physical” actions. IoT will usher automation in a large number of domains, ranging from manufacturing and energy management (e.g. SmartGrid), to healthcare management and urban life (e.g. SmartCity). Applications range from monitoring the moisture in a field of crops, to tracking the flow of products through a factory, to remotely monitoring patients with chronic illnesses and remotely managing medical devices, such as implanted devices and infusion pumps. Forecasts by McKinsey&Company estimate that the economic impact of IoT technology by year 2025 will range from 2.7 to 6.2 trillion dollars [7]. Gartner forecasts predict that by the year 2020 20.8 billions of IoT devices will be installed. Such staggering numbers show that IoT will have a major impact.

However, while on one side, IoT will make many novel

applications possible, on the other side IoT increases the risk of cyber security attacks. In addition, because of its fine-grained, continuous and pervasive data acquisition and control/actuation capabilities, IoT raises concerns about privacy and safety. A recent study by HP about the most popular devices in some of the most common IoT niches reveals an alarmingly high average number of vulnerabilities per device [10]. On average, 25 vulnerabilities were found per device. For example, 80% of devices failed to require passwords of sufficient complexity and length, 70% did not encrypt local and remote traffic communications, and 60% contained vulnerable user interfaces and/or vulnerable firmware [10]. Multiple attacks have already been reported in the past against different embedded devices [2], [16] and we can expect many more in the IoT domain.

2. SECURITY AND PRIVACY RISKS FOR IOT

IoT systems are at high security risks for several reasons. They do not have well defined perimeters, are highly dynamic, and continuously change because of mobility. In addition IoT systems are highly heterogeneous with respect to communication medium and protocols, platforms, and devices. IoT systems may also include “objects” not designed to be connected to the Internet. Finally, IoT systems, or portions of them, may be physically unprotected and/or controlled by different parties. Attacks, against which there are established defense techniques in the context of conventional information systems and mobile environments, are thus much more difficult to protect against in the IoT. The OWASP Internet of Things Project [1] has identified the most common IoT vulnerabilities and has shown that many such vulnerabilities arise because of the lack of adoption of well-known security techniques, such as encryption, authentication, access control and role-based access control. A reason for the lack of adoption may certainly be security unawareness by IT companies involved in the IoT space and by end-users. However another reason is that existing security techniques, tools, and products may not be easily deployed to IoT devices and systems, for reasons such as the variety of hardware platforms and limited computing resources on many types of IoT devices. Even well known encryption protocols, such as RSA, prove to be very expensive when running on devices with limited computing capabilities especially when multiple encryption operations have to be executed concurrently such as in the case of networked vehicles [12], and small drones [14].

Privacy is particularly critical in the context of IoT. As

medical and well-being devices are increasingly being adopted by users and personalized medicine and health care applications are being designed and deployed that rely on continuous fine-grained data acquisition from these devices, the human body is becoming a rich source of information. Such information is typically collected from devices and then uploaded to some cloud and/or transmitted to other devices, such as mobile phones, which in turn may forward the information to other parties. The collected information is typically very rich and often includes meta-data such as location, time, and context, thus making possible to easily infer personal habits, behaviors, and preferences of individuals. It is thus clear that on one side such information has to be carefully protected by all parties involved in its acquisition, management, and use, but also users should be provided with suitable, easy to use tools to protect their privacy and support anonymity depending on specific contexts [11].

3. RESEARCH DIRECTIONS

Developing comprehensive security and privacy solutions for IoT requires revisiting almost all security techniques we may think of. Encryption protocols need to be engineered so to be efficient and scalable for deployment on large-scale IoT systems and devices with limited computational resources. Benchmarks are needed to perform detailed assessments of such protocols [14]. In addition, as devices may be physically unprotected, attackers may have access to the state of the memory while encryption operations are being performed. Addressing such problems may require new techniques based, for example, on white-box cryptography [3]. White-box encryption techniques hide encryption keys by transforming them into large look-up tables in order to make harder for attackers to extract the keys. Such techniques are however very expensive and many of the proposed white-box encryption protocols have been cryptanalyzed. Introducing dynamics in the look-up tables by a shuffling approach [15] may help addressing such problem. In addition, scalability of such protocols is critical, in that in many safety-sensitive applications encryption operations must be very efficient. For example, in a vehicle network, a message from a vehicle informing other vehicles of a sudden break should be processed very quickly in order to give the other vehicles enough time to break. Carefully engineered approaches taking advantage of specialized hardware, such as GPUs, available on systems on chip must be designed and benchmarked [12].

Software running on the devices must also be secured. Major challenges here arise from the fact that many IoT devices are based on processors such as the ARM processor, which have differences in the instruction sets with respect to other conventionally used processors. Such diversity has an implication for example on the techniques for protecting software from attacks, such as return-oriented programming attacks, as such techniques must be tailored to the specific instruction set of the platform of interest [6]. Other research issues concern how to protect at run-time software from memory vulnerabilities. Solutions to this problem may have to take into account the specific programming languages used on IoT devices, such as the case of nesC used in TinyOS, and the resource limitations [8]. Also well-known software management practices, like remote software patching and firmware updates, may become difficult if at all possible in an IoT environment and may actually open the door to additional attacks [5], [4]. Communication protection and defense tech-

niques against novel botnet attacks that exploit IoT devices [8] are also critical.

Data security, availability, and quality are other critical areas for IoT. Data security requires, in addition to the use of encryption to secure the data while being transmitted and at rest, access control policies to govern access to data, by taking into account information on data provenance and meta-data concerning the data acquisition context, such as location and time [9]. Availability requires among other things to make sure that relevant data is not lost. Addressing such requirement entails designing protocols for data acquisition and transmission that have data loss minimization as a key security goal. Kinesis [13] is an example of a sensor network system designed to make it possible for sensors to automatically take response actions in the event of data transmission disruptions. Ensuring data quality is a major critical requirement in IoT as data acquired and transmitted by IoT devices may be of poor quality, because of several reasons such as bad device calibration, device faults, and deliberate attacks aiming at data deception attacks. Solutions like data fusion need to be revised and extended to deal with dynamic environments and large-scale heterogeneous data sources.

Finally privacy introduces new challenges, including how to prevent personal devices from acquiring and/or transmitting information depending on the user location and other context information, and how to allow users to understand risks and advantages in sharing their personal data.

4. CONCLUDING REMARKS

IoT technology introduces several exciting opportunities and new applications. However, it is critical that solutions be adopted to ensure security, privacy, and safety of IoT systems with minimal impact on performance, scalability, and usability. Even though the computer and network security area has offered over the years many important techniques and methods, revisiting and extending these techniques and methods in order to address the specificities of IoT systems entails many scientific and engineering challenges.

Data Processing in Modern Hardware

Gustavo Alonso
Systems Group
Department of Computer Science
ETH Zurich
alonso@inf.ethz.ch

ABSTRACT

Data processing is changing in radical ways from how it has developed in the last four to five decades.

On the one hand, data science and big data have brought an unprecedented growth and variety in data sizes, demanding workloads, data types, and applications. From studying social networks on graph data to genomics over string matching algorithms; from low latency key value stores used to retrieve user profiles to large scale data appliances focusing on data warehousing; from real time stream data processing to database engines on cloud platforms, the types, scope, and requirements on data management engines has grown enormously.

On the other hand, hardware is no longer a source of performance as it has been in the last decades. Instead, it has become a complex, fast evolving, highly specialized, and heterogeneous platform that requires considerable tuning and effort to use optimally. Today, hardware is not becoming necessarily faster per se but provides instead a wide range of options for accelerating and tuning applications through new features. Unlike what happened in the past, applications in general and database engines in particular, have to work much harder to extract performance improvements from new hardware as the exploitation of these new features is not automatic and often requires a redesign of the system. In addition, many of the opportunities offered by modern hardware are still without adequate support from high level tools

such as compilers or debuggers, placing quite a burden on system designers.

In this talk I will discuss the issues in data processing that arise as a result of modern hardware: the need to deal with parallelism and distribution, the increasing importance of networking, the proliferation of accelerators, and the raise of heterogeneity in the machine. These issues are both a threat and a challenge, demanding a radical redesign of many aspects of data processing and database engines. Using examples from recent work ranging from query scheduling to hardware accelerators, I will present several exciting and radically new directions that are opening up for database research as a result of the advances being made in hardware. An important theme in the talk is the call for database designers and researchers to become proactive and identify the hardware features and characteristics that are needed to better support data processing.

ACKNOWLEDGMENTS

I would like to thank all the members of the Systems Group for many informal discussions on the evolution of hardware and data processing over the years that have been instrumental to shape the vision outlined in this keynote.

Finding Users of Interest in Micro-blogging Systems

ABSTRACT

Micro-blogging systems have become a prime source of information. However, due to their unprecedented success, they have to face an exponentially increasing amount of user-generated content. As a consequence finding users who publish quality content that matches precise interest is a real challenge for the average user. This paper presents a new recommendation score which takes advantage both of the social graph topology and of the existing contextual information to recommend users to follow according to user interest. Then we introduce a landmark-based algorithm which allows to scale. The experimental results and the user studies that we conducted confirm the relevance of this recommendation score against concurrent approaches as well as the scalability of the landmark-based algorithm.

1. INTRODUCTION

Micro-blogs have become a major trend over the Web 2.0 as well as an important communication vector. Twitter, the main micro-blogging service, has grown in a spectacular manner to reach more than 570 million users in April, 2014 in less than seven years of existence. Currently around 1 million new accounts are added to Twitter every week, while there were only 1,000 in 2008. 500 million tweets are sent every day and on average a Twitter user follows 108 accounts¹. Facebook is another example with 1.26 billion users who publish on average 36 posts a month. A Facebook user follows on average 130 “friends” which results in 1,500 pieces of information a user is exposed on average when he logs in¹. Other similar systems like Google+, Instagram, Youtube, Sina Weibo, Identi.ca or Plurk, to quote the largest, also exhibit dramatic growth.

¹<http://expandedramblings.com>

This fast and unprecedented success has introduced several challenges for service providers as well as for their users. While the former have to face a tremendous flow of user generated content, the latter struggle to find relevant data that matches their interests: they usually have to spend a long time to read all the content received, trying to filter out relevant information. Two (complementary) strategies have emerged to help the user to find relevant data that matches his interest in the huge flow of user generated content: posts filtering like in [13, 14, 8] and posts/account searches and/or recommendation like in [7, 4, 5]. Social network systems usually offer the ability to search for posts or accounts that match a set of keywords. This could be a “local” search to filter out the posts received, or a “global” search to query the whole set of existing posts/accounts. For the latter search, there exist two options: some pre-computed posts sets that correspond to the hot topics at query time, or customized searches where the query result is built according to the keywords specified by the user. However, the broad match semantics generally adopted by the searching tools is very limited. Even a ranking score based on the number of keywords is not sufficient to retrieve all posts of interest. Combined with the lack of semantics and the number of posts a day, the large number of searches performed every day also raises scalability issue. For instance in 2012, more searches were performed each month (24 billion) on Twitter than on Yahoo (9.4 billion) or on Bing (4.1 billion).

In this paper we consider the problem of discovering quality content publishers by providing efficient, topological and contextual user recommendations on the top of a micro-blog social graph. Micro-blogging systems are characterized by the existence of a large directed social graph where each user (accounts) can freely decide to connect to any other user for receiving all his posts. In this paper we make the assumption that a link between a user u and a user v expresses an interest of u for one or several topics from the content published by v . We consequently choose to model the underlying social network graph as a *labeled social graph*, where labels correspond to the topics of interest of the users. Our objective is to propose a recommendation score that captures both the topological proximity and connectivity of a publisher along with his authority regarding a given topic and the interest of the intermediary users between the one to be recommended and the publisher.

The size of the underlying social graph raises challenging issues especially when we consider operations that involve a graph exploration. In order to speed up the recommendation process we propose a fast approximate computation based on landmarks, *i.e.*, we select a set of nodes in the social graph, called *landmarks*, which will play the role of hubs and store data about their neighborhood. This set of landmarks is selected using different strategies we compare experimentally in Section 5.

Contributions. In this paper we propose a recommendation system that produces personalized user recommendations. Our main contributions are:

- 1) considering the idea that measures based on the graph topology are good indicators for the user similarity, we propose a topological score which integrates semantic information on users and their relationships;
- 2) furthermore, we introduce a landmark-based approach to improve recommendation computation time and to achieve a 2-3 order of magnitude gain compare to the exact computation;
- 3) an experimental validation of our approach, including a comparative study with other approaches (TwitterRank [26] and Katz [16]).

Observe that we illustrate our proposal in the context of micro-blogging systems, but our model is general and may be used for any social networks where users publish content and receive posts from the accounts they follow.

The paper is organized as follows: after the introduction in Section 1, we present the related work in Section 2. Section 3 describes our model and our recommendation scores along with their composition property. Then we propose our fast recommendation computation based on a landmark strategy in Section 4. Our experimental validation is presented in Section 5 while Section 6 concludes the paper and introduces future work.

2. RELATED WORK

Recommendation systems for social networks were recently proposed like [16, 4, 26, 11, 7, 21, 10, 3, 28, 24]. The work in [16] presents a comparison of different topological-based recommendation methods adapted in the context of link-prediction. In [2], authors propose to combine two ranking scores estimated with a fair bets approach on the user invitation graph and on the profile browsing graph. The work in [24] presents a user recommendation system which exploits node similarity scores estimated as a combination of local and global scores. Local score is based on the number of neighbors of the query node and of the recommendation node while global score involved the shortest path between them. Thus the recommendation scores for these approaches are only based on the topology and unlike our proposal do not consider neither content nor authority of the users. On the other side, the work in [20] finds users with high topical authority scores in micro-blogging systems. Unlike our method, those scores are not personalized, the system computes global authority scores, which in our case are used as parameters of the recommendation scores computed for some user.

Other approaches, like [4, 11], consider collaborative filtering. The work in [4] introduces a collaborative tweet ranking based on preference information of the users, authority of the publisher and the quality of the content. Recommendations are produced at a tweet level. Hannon et al. [11] evaluate a set of profiling strategies to provide user recommendations based on content, *e.g.* the tweets of the user or the tweets of his followers, or collaborative filtering. The methods proposed by [21] and [7] also provide tweet recommendations. Pennacchiotti et al. [21] analyze the tweets content as well as the content of the user’s direct neighbors while Diaz-Aviles et al. [7] use the user past interaction to compute rankings in real-time. All these works consider content but unlike our proposal they do not consider paths longer than direct follower/followee links.

Few papers combine content and topology of the social graph. Wend et al. [26] present an extension of the PageRank algorithm named TwitterRank which captures both the link structure and the topical similarity between users. However this similarity is based on topics provided by LDA and their distance-based similarity computation between users does not capture the semantic similarity between topics. We also propose an authority score for an account which estimates the local and global influence of this account for a given topic. Our scoring function also provides higher weight for short paths to favor “local” recommendations. In [10], authors describe the production recommender system implemented in *Twitter*. It relies on an adaptation of the SALSA algorithm [15] which provides user recommendation in a centralized environment based on a bipartite graph: the user’s circle of trust, computed with random walks from the user considering content properties, and the accounts followed by the users from the circle of trust (the authorities). Our approach is different since it captures the users interest through the labeled social graph, which allows to compute scores based on semantics, on authority and on topology.

To scale and to accelerate our recommendations computations, we pre-compute scores for a subset of nodes named landmarks. Landmark-based approach is a well-known *divide-and-conquer* strategy for the shortest paths problem that have been shown to scale up to very large graphs [25, 9, 22, 23]. The idea is to select a set L of nodes as landmarks which store the distance to other nodes. The distance $d(u, v)$ between two nodes u and v is then estimated by computing the minimum $d(u, l) + d(l, v)$, where $l \in L$. Das Sarma et al. [23] chose to pre-compute the time-consuming shortest-path operations for each node in structures called “sketches” and to use them to provide shortest-path estimations at query-time which enables scaling for large web graphs. Gubichev et al. [9] extend the sketch-based algorithm proposed by [23] to retrieve shortest paths and improve the overall accuracy. Tretyakov et al. [25] use shortest-path trees to achieve an efficient and accurate estimation which support updates. They also introduce a landmark selection strategy that attempts to maximize the shortest-paths coverage. In [22] authors also investigated the impact of landmark selection on the accuracy of distance estimations. They proved that optimizing the landmark coverage is a NP-hard problem and showed experimentally that clever landmark selection strategies yield better results. Similar to these approaches, we employ landmarks for computation scaling and use some of the existing landmark selection strategies in the context of user recommendation.

3. MODEL

We introduce in this section the underlying social graph model and our recommendation scores. Table 1 lists the different notations used throughout the paper.

N, E	resp. set of nodes and edges
$\Gamma^u, \Gamma^u(t)$	followers for u (resp. total or on topic t)
\mathcal{T}	topics vocabulary
$label_n, label_e$	labeling function for nodes and for edges, resp.
$topo_\beta(u, v)$	topological score of v for u with decay factor β
$\sigma(u, v, t)$	recommendation score of v for u on topic t
$\widetilde{\sigma}_S(u, v, t)$	approximate recommendation score considering paths going through a node $n \in S$
$\omega_p(t)$	topical component of the path score for path p
$\bar{\omega}_p(t)$	path score for path p
$auth(u, t)$	node authority score for u on topic t
$\varepsilon_e(t)$	edge relevance of edge e on topic t
α, β	decay factor for an edge and path resp.
λ, \mathcal{L}	a landmark, the set of landmarks
$P_{u,v}$	set of all paths between u and v
$P_{u,\lambda,v}$	set of all paths between u and v through λ
$\Upsilon_k(\lambda)$	the k -vicinity of λ
$R_{u,v}$	recommendation vector of v for u for all topics

Table 1: List of notations

3.1 Labeled social graph

We model the *Twitter* social network as a directed labeled graph $G=(N, E, \mathcal{T}, label_N, label_E)$ where N is set of vertices such that each vertex $u \in N$ is a user (account). $E \subseteq N \times N$ is a set of edges where an edge $e = (u, v) \in E$ exists if u follows v , i.e., u receives the publications of v . The labeling function $label_N : N \rightarrow 2^{\mathcal{T}}$ maps each user to the set of topics that characterize his posts, chosen in a topic vocabulary \mathcal{T} . The topics associated by the labeling function $label_E : E \rightarrow 2^{\mathcal{T}}$ to an edge $e = (u, v)$ describe the interest of the user u for the posts of v . In this paper topics are extracted from tweets by using OpenCalais¹ combined with a trained Support Vector Multi-Label Model using Mulan² (see Section 5). For a user u , we define $\Gamma^u(t)$ the set of nodes following u on topic t and by Γ^u the set of all his followers. An example of such graph is depicted in Figure 1. For users B and C we display their topics of interest along with an excerpt of their tweets.

3.2 Recommendation

For a user u and a query composed of several topics $Q = \{t_1, \dots, t_n\}$, our model recommends users v based on the following criteria which consider both graph topology and content semantics:

- (i) *user proximity*: u trusts his friends, the friends of his friends, etc., but this confidence decreases with distance ;
- (ii) *the number of paths* from u to v : user v is likely to be more important for u if there are many other relevant users (i.e., linked to u) who recommend v ;
- (iii) *topical path relevance* of the connections between u and v with respect to Q .

¹<http://www.opencalais.com/>

²<http://mulan.sourceforge.net/>

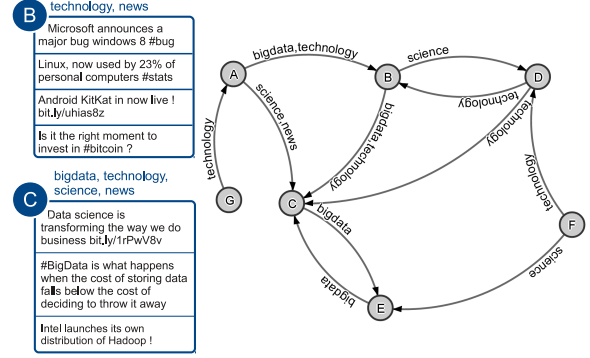

Figure 1: A labeled social graph

Our recommendation score combines the topical relevance of paths with a topological measure which considers *all existing paths* between two nodes u and v of the graph. More precisely, the recommendation score $\sigma(u, v, t)$ of the user v for user u on topic t on paths $p = u \rightsquigarrow v$ is the sum of all path scores $\bar{\omega}_p(t)$ and is expressed as follows:

DEFINITION 1 (RECOMMENDATION SCORE).

$$\sigma(u, v, t) = \sum_{p \in P_{u,v}} \bar{\omega}_p(t) = \sum_{p \in P_{u,v}} \beta^{|p|} \omega_p(t) \quad (1)$$

where $P_{u,v}$ denotes the set of all paths between u and v , $\bar{\omega}_p(t)$ is the total path score of a path of length $|p|$ and $\omega_p(t)$ the topical relevance $\omega_p(t)$. The decay factor $\beta \in [0, 1]$ gives more importance to shorter paths.

The final recommendation score for the query Q is computed as a weighted linear combination (some are proposed in [1]) where user scores for each individual topic $t_i \in Q$ are weighted by the relevance of t_i for the posts of u which is computed by the topic extraction method (see Section 5).

Note that we can deduce from Equation 1 a score which considers only the topology by ignoring the topical relevance of paths (i.e. setting $\omega_p(t)$ to 1). This score is higher if there exist many short paths between u and v and is denoted as :

$$topo_\beta(u, v) = \sum_{p \in P_{u,v}} \beta^{|p|} \quad (2)$$

It corresponds to the Katz score [16] that has been successfully employed for link prediction. We will use it as a baseline for comparison with our method in Section 5.

The topical relevance $\omega_p(t)$ of a path $p = u \rightsquigarrow v$ for a topic t in Equation 1 considers both the relevance of nodes (*user authority*) and the topical relevance of edges (*edge relevance*) on the path p w.r.t the topics of the query Q . We define in the following these concepts.

Edge relevance:.

Each edge on a path p contributes to the score of p with a semantical score which depends on its topics. Distant edges contribute less to the recommendation score than edges close to u . More precisely, the relevance of an edge e at distance d from u on path p for a topic t is defined as :

$$\varepsilon_e(t) = \alpha^d \times \max_{t' \in label_E(e)} (sim(t', t)) \quad (3)$$

where $label_E(e)$ is the labeling function that returns the topics associated to the edge e . The decay factor $\alpha \in [0, 1]$ decreases the influence of an edge according to its distance from u . The function $sim : \mathcal{T}^2 \rightarrow \mathbb{R}$ computes the semantic similarity between two topics t and t' . We use in the present paper the Wu and Palmer similarity measure [27] on top of the WORDNET³ database (we have a small number of topics for labeling our dataset without synonymy issues), but other semantic distance measures, such as RESNIK or DISCO⁴ could also be used. The choice of the best similarity function is beyond the scope of the current paper. When an edge is labeled with several topics, we only keep the maximum similarity to t among all its topics to avoid high scores for edges labeled with many topics that have small similarity to t .

User authority:

We define a per node topical authority function $auth(u, t)$ of u on a topic t which depends on the number of users who follow u on t . The authority score is decomposed into two scores: (i) the *local authority score* that gives a higher score to users that are specialized on topic t than to users u who publish on a broad range of topics and (ii) the *global popularity score* that gives higher scores to users that are more followed on t . Combination of local and global scores has also been used to compute authorities for Web pages [12] or micro-blogging [10]. The authority score $auth(u, t)$ of a user u on a topic t is consequently defined as follows :

$$auth(u, t) = \underbrace{\frac{|\Gamma^u(t)|}{|\Gamma^u|}}_{local} \times \underbrace{\frac{\log(1 + \Gamma^u(t))}{\log(1 + \max_{v \in N}(\Gamma^v(t)))}}_{global}$$

where $|\Gamma^u(t)|$ is the number of followers of u on t , and $|\Gamma^u|$ is its total number of followers. We used the logarithm function to smooth the difference between popular accounts and accounts with very few followers. The local authority is 1 when u is followed exclusively on t and the global popularity is 1 when u is the most followed user on t . If no other user follows u on t both scores are 0. The authority scores for a given topic t are high for users that are mainly followed on topic t and that have a significant number of followers. The combination of both local and global scores leads to similar authority scores for very specialized accounts with few followers and for very popular but generalist accounts. Observe for scores update that $|\Gamma^u|$ and $|\Gamma^u(t)|$ can be computed on local information of each user, without graph exploration. Oppositely the computation of $\max_{v \in N}(\Gamma^v(t))$ may be costly since it requires to query the complete graph. However, the log strongly limits the impact of a variation in the popularity of an account with millions of followers, and we can assume this value is stored (and re-computed periodically).

EXAMPLE 1 (LOCAL AND GLOBAL AUTHORITY). Consider the example graph in Figure 1, with a sample of tweets for the users B and C along with their topics. User B is more relevant for technology than C . Indeed B and C have the same global popularity with two followers on this topic for both accounts. However the local authority of B on technology is

higher than the one of C since 2 out of the three topics on which B is followed are technology, whereas for C only 2 out of the 6 topics on which it is followed are technology. For the topic bigdata, the local authority of B and C is the same (1 out of 3 for B and 2 out of 6 for C) but C is more followed on bigdata (2 users who follow him) than B (1 user). Therefore, the total authority of C on bigdata is higher.

Topical path relevance:

Finally, we consider that the path relevance of p is high when both the relevance of the nodes and the one of the edges of p are high:

$$\omega_p(t) = \sum_{e \in p} \varepsilon_e(t) \times auth(end(e), t) \quad (4)$$

where $end(e)$ returns the end node of the edge e . The recommendation score of v for the user u on topic t is then obtained by replacing $\omega_p(t)$ in equation (1) by its formula given by equation (4). The resulting user recommendation score thus captures the topology (proximity and connectivity) of the graph along with the followers interests (expressed as labeled edges) and the authority score regarding the topic of interest for each user on the path.

EXAMPLE 2 (TOPICAL PATH RELEVANCE). In Fig. 1, we want to recommend to A users on the topic technology (we suppose a search within a range $k = 2$). Users D and E can be reached with respectively the paths $p_1 = A \rightarrow B \rightarrow D$ and path $p_2 = A \rightarrow C \rightarrow E$, each of length 2. The relevance of the edge $A \xrightarrow{bigdata, technology} B$ is higher than the one of $C \xrightarrow{bigdata} E$, since the first one is at distance 1 from A , whereas the second is at distance 2. Moreover, the authority of node B on technology (computed as $(local) \times (global) = \frac{2}{3} \times \frac{\log(1+2)}{\log(1+2)}$) is higher than the authority of C on technology ($\frac{2}{6} \times \frac{\log(1+2)}{\log(1+2)}$). Overall, the semantic relevance of the edges on p_1 for technology is higher than the one of edges on p_2 and D obtains a higher recommendation score than E .

3.3 Score analysis

We will show in the following the iterative formula for score computation and the score composition property that is used in Section 4 for landmark-based computation.

Iterative score computation.

Recommendation scores $\sigma(u, v, t)$ (Equation 1) are computed by using the Power Iteration algorithm [19] (see Algorithm 1 in Section 4). It starts by initializing $\sigma(u, u, t) = 1$ and $\sigma(u, v, t) = 0$ ($\forall u \neq v$). At each step i , a new score $\sigma(u, v, t)^{(i)}$ (that considers all paths from u to v with length $\leq i$) is computed by using the scores $\sigma(u, v, t)^{(i-1)}$ of the neighbors $w \in \Gamma^v$ computed at step $(i-1)$. The computation is performed until convergence. The iterative formula for score computation is the following :

PROPOSITION 1 (ITERATIVE COMPUTATION).

$$\sigma^{(i)}(u, v, t) = \sum_{w \in \Gamma^v} (\beta \cdot \sigma^{(i-1)}(u, w, t) + topo_{\alpha\beta}^{(i-1)}(u, w) \cdot \bar{\omega}_{w \rightarrow v}(t)) \quad (5)$$

where $topo_{\alpha\beta}^{i-1}(u, w)$ is the topological score (see Equation 2) with a decaying factor of α, β . The score $\bar{\omega}_{w \rightarrow v}(t) = \beta \cdot \alpha$.

³<http://wordnet.princeton.edu/>

⁴http://www.linguatools.de/disco/disco_en.html

$\max_{t' \in \text{label}_E(w \rightarrow v)}(\text{sim}(t', t)).\text{auth}(v, t))$ is the score of a path that contains only the edge $w \rightarrow v$ with topic t .

PROOF. Suppose a path p of length $k \leq i$ from u to v . This path can be decomposed into a path p_1 of length $k-1$ from u to the neighbor w of v and an edge e from w to v of length 1. By using Equations (3) and (4), the score $\bar{w}_p(t)$ is computed as: $\bar{w}_p(t) = \beta \cdot \bar{w}_{p_1}(t) + \beta^{|\bar{p}_1|} \cdot \alpha^{|\bar{p}_1|} \cdot \bar{w}_e(t) = \beta \cdot \bar{w}_{p_1}(t) + \beta^{k-1} \cdot \alpha^{k-1} \cdot (\beta \cdot \alpha \cdot \max_{t' \in l_e(\text{edge})}(\text{sim}(t', t)).\text{auth}(v, t))$. The score $\bar{w}_{p_1}(t)$ corresponds to a path that finishes at w .

We can re-organize the paths in Equation 1 by grouping those that pass through the same neighbor w of v : $\sigma(u, v, t) = \sum_{p \in P_{u,v}} \bar{w}_p(t) = \sum_{w \in \Gamma^{v-}(t)} (\sum_{p \in P_{u,v}, w \in p} \bar{w}_p(t))$. By replacing $\bar{w}_p(t)$ into this equation we obtain the iterative score formula. \square

Score composition.

From the iterative score computation we can deduce for each path p from a node u to a node v its total path score $\bar{w}_p(t)$ on topic t from the score of its sub-paths already computed using the following property :

PROPOSITION 2 (RECOMMENDATION SCORE COMPOSITION). Assume a path $p = p_1.p_2$, with $\bar{w}_{p_1}(t)$ and $\bar{w}_{p_2}(t)$ the total path scores of respectively p_1 and p_2 for a topic t . The total path score of p can be computed as:

$$\bar{w}_p(t) = \beta^{|\bar{p}_2|} \cdot \bar{w}_{p_1}(t) + \beta^{|\bar{p}_1|} \cdot \alpha^{|\bar{p}_1|} \cdot \bar{w}_{p_2}(t)$$

PROOF. By induction using the recursive formula, we prove the proposition for paths with length $k \geq 1$. \square

Iterative score computation convergence.

In order to show the convergence of the iterative computation of recommendation scores $\sigma(u, v, t)$ of users v for user u on topic t (Equation (5)), we express this computation in matrix form as :

$$R_t^{(k+1)} = (\beta A) R_t^{(k)} + (\beta \alpha) S_t T_{\alpha\beta}^{(k)} \quad (6)$$

where $R_t^{(k)}$ is the recommendation vector for topic t computed at step k ($R_t^{(k)}[v]$ is the recommendation score $\sigma(u, v, t)$ computed at step (k)). Matrix A is the adjacency matrix of the graph ($A[v][u] = 1$ if u follows v). Matrix S_t is the similarity-authority matrix ($S_t[v][u] = \text{sim}(\max_{t' \in l_e(u \rightarrow v)}(t', t)) \times \text{auth}(v, t)$). Vector $T_{\alpha\beta}^{(k)}$ is the topological vector at step k ($T_{\alpha\beta}^{(k)}[v]$ is the topological score $\text{topo}_{\alpha\beta}^{(k)}(u, v)$). It can be expressed as follows :

$$T_{\alpha\beta}^{(k+1)} = \alpha\beta A T_{\alpha\beta}^{(k)} + I$$

where $I[u] = 1$ and $I[v] = 0$ for all $u \neq v$. We deduce that the computation convergence is achieved under the following condition :

PROPOSITION 3 (SCORES COMPUTATION CONVERGENCE). If $\beta < 1/\sigma_{\max}(A)$, where $\sigma_{\max}(A)$ is the highest eigen value for A , then the iterative scores computation of our recommendation scores converges.

PROOF. Based on the recursive formula which defines the topical vector for a given node n , the topical scores matrix defined by the series expansion

$$T_{\alpha\beta} = \sum_{i=1}^{\infty} \alpha\beta^i A^i = (I - \alpha\beta A)^{-1} - I$$

converges when $I - \alpha\beta A$ is positive definite, so $\alpha\beta < 1/\sigma_{\max}(A)$. Consider a step k' when convergence is reached for $T_{\alpha\beta}$. Then for any $k > k'$, we have the recursive computation $R^{(k+1)} = (\beta A) R^{(k)} + C$ with $C = (\alpha\beta) S T_{\alpha\beta}^{(\infty)}$ constant. The convergence for $R^{(k+1)}$ is reached when $R^{(\infty)} = (\beta A) R^{(\infty)} + C$ thus when $R^{(\infty)} = (I - \beta A)^{-1} \times C$. This can be achieved if $\beta < 1/\sigma_{\max}(A)$. Since $\beta > \alpha\beta$, this later condition is sufficient to ensure convergence. \square

4. LANDMARK-BASED COMPUTATION

The recommendation score computation presented in the previous section assumes to explore *all* paths from a user u to the nodes to be recommended. Computing recommendation scores by graph exploration at k hops for a graph with n nodes supposes to consider out_{avg}^k paths for the average case (out_{avg} denotes the average out degree) and of N^k paths in the worst case for a complete graph. This might be prohibitive in the context of social graphs with millions of nodes and edges. We rely here on a landmark-based approach to propose fast approximate recommendations.

The computation is performed in two steps: (i) in the preprocessing step we precompute for a sample of nodes in the graph, named landmarks, top- n recommendation scores (n being a parameter of the system) for every topic $t \in \mathcal{T}$ and (ii) at query time we compute approximate recommendations by exploring the graph until a given depth (also a parameter of the system) and collect precomputed recommendations from landmarks encountered during this exploration.

Figure 2: Landmark-based recommendation

EXAMPLE 3. Figure 2 illustrates this approach, where n is the query node and $\lambda_1, \lambda_2, \lambda_3$ and λ_4 are landmarks. When performing the graph exploration represented by the blue dashed-line from the node n , the landmarks λ_1, λ_2 and λ_4 are encountered. Node r_2 is encountered during exploration and its score for n is computed at the same time as the scores for λ_1, λ_2 and λ_4 . r_1 is not encountered during the exploration from n , but it is encountered by the explorations starting from landmarks λ_1 and λ_2 . Its recommendation score for n is estimated by aggregating the scores of λ_1 and λ_2 for n computed at query time with the scores of r_1 for λ_1 and λ_2 which were precomputed.

4.1 Preprocessing

For the preprocessing step we consider a subset $\mathcal{L} \subset N$ of nodes, so-called the landmarks, with $|\mathcal{L}| \ll |N|$. Instead of a random sampling, several strategies may be considered to determine \mathcal{L} . For instance, landmark-based approaches for computing shortest paths within a large graph rely mainly on centrality properties (betweenness or closeness centrality) to determine the sampling. The publisher-follower characteristics of our graph also allow other topology-based sampling, like a selection of the nodes with the most important number of followers (most popular accounts) or the ones that follow the highest number of accounts (most active readers). While the choice of the landmarks may impact the global performances of our approach we do not investigate further the sampling strategies in the current paper. Nonetheless some of these sampling techniques are experimentally compared in Section 5.

Algorithm 1: LANDMARK_RECOMM($\lambda, max_k, T, \beta, n$)

Require: landmark (λ), maximum exploration (max_k), set of topics (T), topological decay factor (β), number of results to return (n)

Ensure: a set of recommendation list R_λ , a topological vector $topo_\beta(\lambda)$

```

1:  $\Upsilon_0 := \lambda, k := 0$ 
2: while  $k < max_k$  and  $converged = false$  do
3:    $\Upsilon_{k+1} := \emptyset$ 
4:   for all  $u \in \Upsilon_k$  do
5:      $\Upsilon_{k+1} := \Upsilon_{k+1} \cup \Gamma^u$ 
6:     for all  $v \in \Gamma^u$  do
7:       for all  $t \in T$  do
8:          $\sigma^{(k+1)}(\lambda, v, t) +=$ 
            $\beta \times \sigma^{(k)}(\lambda, u, t) + topo_{\alpha\beta}^k(\lambda, u) \times \overline{w}_{u \rightarrow v}$ 
9:       end for
10:       $topo_{\beta}^{(k+1)}(\lambda, v) += \beta \times topo_{\beta}^k(\lambda, u)$ 
11:     end for
12:      $R_t[u] += \sigma^{(k)}(\lambda, u, t)$ 
13:      $topo_{\beta}(\lambda, u) += topo_{\beta}^k(\lambda, u)$ 
14:   end for
15:   if  $(\sum_{u \in \Upsilon_k} \sigma^k(\lambda, u, t)) / |R_t| < tol, \forall t \in T$  then
16:      $converged := true$ 
17:   end if
18:    $k := k + 1$ 
19: end while
20: return for all  $t \in T$  top-n( $(R_t), topo_{\beta}(\lambda)$ )

```

Algorithm 1 performs the recommendation computation (we remove the initialization of recommendation scores to simplify the presentation) and is used both in the preprocessing and in the approximate score computation step. It takes as parameters the starting node λ of the graph exploration, the maximum exploration depth max_k , the set of topics on which the recommendations are computed T , the path decay factor β and the number n of final results to be kept.

The set of reached nodes at depth k from λ is called the k -vicinity of λ , denoted $\Upsilon_k(\lambda)$. $\Upsilon_\infty(\lambda)$ denotes the set of reachable nodes from λ . For each topic $t \in T$ the algorithm computes a recommendation vector R_t with $R_t[u] = \sigma(\lambda, u, t)$ (see Equation 6), where $u \in \Upsilon_\infty(\lambda)$ is a reachable node from λ . The algorithm also computes the topological scores $topo_\beta(\lambda, u)$ with decay factor β for all $u \in \Upsilon_\infty$ (Equation 2), used to estimate the final recommendation scores at query time (see below). Iteration in line 4 allows to ex-

plore the k -vicinity of λ . For each iteration we add in the k -vicinity nodes that could be reached with an additional hop (l. 5). For each node v reached at this step (l. 6), we compute (or update if the node has been already encountered) the recommendation score for each term of the topic vocabulary (l. 7-8), and the node's topological score (l. 10). The score for u on paths of length k is added to the sorted topical (l.12) and topological (l.13) lists of λ . Finally, only the top- n recommendations for each vector R_t and only the top- n topological scores $topo_\beta(\lambda)$ are stored.

In the preprocessing step, for each landmark $\lambda \in \mathcal{L}$ we compute the recommendation scores on all topics for all nodes encountered during the iterative computation. So Algorithm 1 runs until the convergence is reached (max_k is set to a large value) with the parameter T set to \mathcal{T} .

4.2 Fast approximate recommendation

We now present the algorithm for fast approximate recommendations based on the pre-computations performed for each landmark in the preprocessing step. We assume that we want to recommend to an account u other accounts for a topic t .

We first perform a graph exploration starting from u , similar to the one described by the Algorithm 1, for a given maximal depth k , max_k , set to a small value (e.g. 2 or 3). The graph exploration finds landmarks in the k -vicinity of u and computes path scores on topic t for paths from u to each encountered landmark. These scores are further combined with the scores stored by the landmarks in order to compute the approximate recommendation scores.

More precisely, we denote $\Lambda \subseteq \mathcal{L}$ the set of landmarks encountered by the graph exploration. For each $\lambda \in \Lambda$ the top- n recommended accounts v along with their recommendation scores $\sigma(\lambda, v, t)$ and their topological score $topo_\beta(\lambda, v)$ are already computed in the preprocessing step. The approximate recommendation of a node v for a user u is an aggregation of the scores of v computed by all the landmarks $\lambda \in \Lambda$:

DEFINITION 2 (APPROXIMATE RECOMMENDATION SCORE).
The approximate recommendation score of a node v for a node u on the topic t with respect to the set of landmarks Λ is defined as :

$$\tilde{\sigma}_\Lambda(u, v, t) = \sum_{\lambda \in \Lambda} \tilde{\sigma}_\lambda(u, v, t)$$

where the score $\tilde{\sigma}_\lambda(u, v, t)$ denotes the score of v that takes into consideration the set of paths $P_{u, \lambda, v}$ from u to v that pass through the landmark λ .

The score $\tilde{\sigma}_\lambda(u, v, t)$ is computed by the composition of the scores $\sigma(u, \lambda, t)$ and $topo_{\beta\alpha}(u, \lambda)$ obtained during the exploration phase with the scores $\sigma(\lambda, v, t)$ and $topo_\beta(\lambda, v)$ that are stored in the sorted lists of λ .

PROPOSITION 4 (APPROXIMATE SCORE COMPUTATION).
The recommendation score of v for u with respect to the landmark λ can be computed as follows :

$$\tilde{\sigma}_\lambda(u, v, t) = \sigma(u, \lambda, t) \times topo_{\beta\alpha}(\lambda, v) + topo_{\beta\alpha}(u, \lambda) \times \sigma(\lambda, v, t)$$

PROOF. Any path p from $P_{u, \lambda, v}$ could be decomposed into p_1 and p_2 , with $p_1 \in P_{u, \lambda}$ and $p_2 \in P_{\lambda, v}$. Obviously any path $p = p_1.p_2$ with $p_1 \in P_{u, \lambda}$ and $p_2 \in P_{\lambda, v}$ is a path from $P_{u, \lambda, v}$.

Consequently, based on Proposition 2) we have:

$$\begin{aligned}
\tilde{\sigma}_\lambda(u, v, t) &= \sum_{p \in P_{u, \lambda, v}} \bar{\omega}_p(t) \\
&= \sum_{p_1 \in P_{u, \lambda}} \sum_{p_2 \in P_{\lambda, v}} \beta^{|p_2|} \cdot \bar{\omega}_{p_1}(t) + \beta^{|p_1|} \cdot \alpha^{|p_1|} \cdot \bar{\omega}_{p_2}(t) \\
&= \sum_{p_1 \in P_{u, \lambda}} \bar{\omega}_{p_1}(t) \cdot \sum_{p_2 \in P_{\lambda, v}} \beta^{|p_2|} + \sum_{p_1 \in P_{u, \lambda}} (\beta \cdot \alpha)^{|p_1|} \cdot \sum_{p_2 \in P_{\lambda, v}} \bar{\omega}_{p_2}(t) \\
&= \sigma(u, \lambda, t) \cdot \text{topo}_\beta(\lambda, v) + \text{topo}_{\beta \cdot \alpha}(u, \lambda) \cdot \sigma(\lambda, v, t)
\end{aligned}$$

□

Note that our approach estimates a lower-bound of the recommendation scores while landmark-based approaches traditionally proposed for shortest paths computation provide score upper-bounds, based on the triangular inequality. Indeed in our setting the approximate scores do not consider all the paths from u to v , but only the subset $P_{u, \lambda, v}$ that pass through λ . However experiments show this approximation allows to retrieve a set of recommendations close to the one retrieved by an exact computation.

Algorithm 2: APPROX_RECOMM(u, k, t, β, α)

Require: a node u , a max. depth k , a topic t , the decay factor for path β and for edge α .

Ensure: an ordered list of recommendations \tilde{R}_t for u

```

1: ( $R_t, \text{topo}_{\beta \cdot \alpha}(u)$ )  $\leftarrow$  LANDMARK_RECOMM( $u, k, t, \beta, \alpha$ )
2: for all  $v \in R_t$  do
3:   if  $v \in \mathcal{L}$  then
4:     for all  $w$  recommended by  $v$  do
5:        $\tilde{R}_t[w] +=$ 
6:          $\sigma(u, v, t) \cdot \text{topo}_\beta(v, w) + \text{topo}_{\beta \cdot \alpha}(u, v) \cdot \sigma(v, w, t)$ 
7:     end for
8:   end if
9: end for
9: return  $\tilde{R}_t$ 

```

We perform our approximate recommendation for a node u and a topic t by using Algorithm 2. It first calls the LANDMARK_RECOMM algorithm to compute recommendation scores from u to all nodes within a distance k along with their topological score (l. 1). Observe that unlike the preprocessing step, the exploration depth has a small value k (2 in our experiments) so that the algorithm will not be run until the convergence. The recommendations are computed only for a single topic t . Note also that the decay factor is here $\beta \cdot \alpha$. For each encountered landmark (l. 2-3) we combine its recommendation for the topic t with the recommendation score computed from u to the landmark according to Proposition 4 (l. 5).

5. EXPERIMENTS

In this section we present the experiments that we have conducted on a real *Twitter* and *DBLP* datasets to validate our structures and algorithms.

5.1 The datasets

The Twitter dataset we use in our experiments contains approximately 2.2 million users (with their 2.3 billion associated tweets acquired in 2015 from February to April) linked by more than 125 million edges (*i.e* following relationships).

Table 2 describes the main topological properties on the generated dataset. For our *Twitter* dataset these properties are

Property	Twitter	DBLP
Total number of nodes	2,182,867	525,567
Total number of edges	125,451,980	20,526,843
Avg. out-degree	57.8	47.3
Avg. in-degree	69.4	53.6
max in-degree	348,595	9,897
max out-degree	185,401	5,052

Table 2: Datasets topological properties

very close to the ones of the real *Twitter* network observed in [18].

Topic extraction:

As already mentioned, in order to generate the topics of the edges we first used the OpenCalais document categorization to tag a subset of the users (nodes) in our graph with topics extracted from their published tweets. This strategy allowed to tag 10 percents of our nodes using a list of 18 standard topics for Web sites/documents proposed by OpenCalais. The user categorization was completed by using a trained Support Vector Multi-Label Model using Mulan, with a precision of 0.90, that associated to each user in the graph his publisher profile (topics on which he publishes). Each follower is characterized by a follower profile containing topics with high frequency among the topics of their followed publishers. Finally the labels of each edge are the topics in the intersection between the corresponding follower and publisher profiles. The resulting graph is a fully labeled social graph with 2.2M nodes and 125M edges. We refer to this dataset as *Twitter*. The edge labels obtained with our generation method show a biased distribution similar to the one observed for Web sites in Yahoo! Directory [17] (see Figure 3).

Figure 3: Distribution of edges per topic

For the DBLP dataset, we merged different versions of the ArnetMiner DBLP datasets⁵. The resulting dataset contains 2,291,100 papers, 1,274,860 authors and 4,191,643 citations. From this dataset we build a graph of author citations by creating a directed edge between author u and author v if some paper of u cites a paper of v . This results in a final dataset with 525,567 authors and 20,526,843 citations

⁵<http://aminer.org/billboard/citation>

between them. Observe that we only kept cited authors. Then we used the Singapore Classification⁶ to manually label some of the major conferences. The other conferences are labeled based on the number of authors they have in common with already labeled conferences (topics of two conferences are close if there are many authors that publish in both of them). Paper topics are deduced from the conference topics by assuming that a paper published in a conference is about the main topic of this conference. Author profiles are built from the topics of their published papers. The resulting dataset is summarized in Table 2.

5.2 Implementation

We implemented our solution in Java (JVM version 1.7). The experiments were run on a 64-bit server with a 10 cores Intel Xeon processor at 2.20GHz and 128GB of memory. The server is running Linux with a 3.11.10 kernel.

The topic similarities given by the Wu and Palmer similarity scores are pre-computed and stored in memory as a triangular similarity matrix. We considered here only the 18 common topics for Web documents, which results in a 2.5 KB file, but observe that for 10,000 topics the similarity matrix will require around 750MB so can still easily fit in memory. A similar approach was chosen for the similarity matrix of the DBLP dataset. We stored the landmark recommendations as inverted lists: for each landmark, we have a set of accounts recommended along with their recommendation score for each topic from \mathcal{T} . Landmarks were chosen according to one of the selection strategies presented in Table 4. We compare the quality of our recommendations with two related algorithms chosen as baseline: the standard Katz score [16], which considers only the topology (all paths between two accounts along with their length, given by the topological score in Equation 2), and TwitterRank [26] which captures both the link structure and the topical similarity between users. In the following we denote our score as TR.

The values of parameter β and α are set to 0.0005 and respectively to 0.85, similarly to the values used for the Katz and the TwitterRank algorithms in [16] and [26].

5.3 Quality of the recommendation

We consider a test set of T edges of the graph together with their corresponding topics representing the ground truth. As observed in [16], to maintain the topological properties of the graph during the evaluation process, the target node of an edge of the test set must have at least k_{in} in-degree and the source node at least k_{out} out-degree ($k_{in} = 3$ and $k_{out} = 3$ in our experiments). All edges from T are then removed from the graph. For each edge $e = u \rightarrow v$ in T we randomly select 1000 accounts in the graph. We compute recommendation scores for the 1001 accounts (the 1000 accounts and v) with respect to u on the topics of e and we form a ranked list (similar to [6]) for each topic. For each list, if v belongs to the $top-n$ accounts of the ranked list we have a hit, otherwise a miss. The overall recall and precision are defined similarly to [6] with $\#hits/T$ and $\#hits/N.T$ respectively. For our experiments we set the test size $T = 100$ and we average values over 100 trials.

Figure 4 illustrates the accuracy of the different recommendation strategies for the Twitter dataset. We see that

Figure 4: Recall at N (Twitter)

TwitterRank is outperformed by other algorithms. Indeed only for 4% of the recommendations the account corresponding to the removed edge is found in the top-1 for TwitterRank, while Katz provides as first recommendation the correct account in 29% of the tests and TR in 34%. So TR provides a 8.5 and 1.2 gain with TwitterRank and Katz respectively for the top-1. For the top-10 the improvement remains significant: 3.8 and 1.3 with TwitterRank and Katz respectively.

Figure 5: Precision vs recall (Twitter)

Figure 5 confirms that TR outperforms other approaches: for a similar recall value greater than 0.4, the precision of TR is at least twice the one of Katz and one order of magnitude higher than the one of TwitterRank.

Figure 6: Recall at N (DBLP)

We observe in Figures 6 and 7 that the DBLP dataset exhibits similar results. The recall however exhibits a faster

⁶<http://www.ntu.edu.sg/home/assourav/crank.htm>

Figure 7: Precision vs recall (DBLP)

increase for TR due to the self-citations phenomenon: authors from a given paper often cite one or several of their previous papers on the topic. These papers may share some citations with the paper corresponding to the edge removed for the selected author. This also explains the faster recall increase for Katz strategy. TwitterRank whose recommendations are essentially based on the popularity (in-degree) of an account reached in the graph does not capture this phenomenon and provides slightly worse results than with the Twitter dataset.

Figure 4 also illustrates the benefit when taking into account both the edge similarity and the authority. Adding the edge similarity to Katz, which takes into account only the topology (number and length of the paths between two nodes), provides a better precision and recall (+11% for the precision and $N = 20$, see TR-auth). When we consider our approach without edge-similarity scores, but with topic authorities of the nodes, we improve both recall and precision (+25% compare to Katz precision, see TR-sim). Finally our approach which integrates the topology, the edge similarity and the topic authorities, outperforms these approaches (+32%, +19% and +6% with resp. Katz, TR-auth and TR-sim).

However there exists a large discrepancy for accuracy when considering two dimensions of analysis: the edge removal strategy and the popularity of the topic used for the recommendation. For the top-10, Figure 8 shows that for Twitter we have a very low accuracy, *i.e.* a recall of 0.15, 0.03 and 0.18 for respectively Katz, TwitterRank and TR, when trying to retrieve an account which belongs to the top-10% less followed accounts (TW min). Conversely very popular accounts (top-10% most followed accounts) are most of time retrieved in the top-10 recommendations with a recall between 0.9 and 0.95 for all strategies. This can be explained by their path-based approach which aggregates scores on incoming paths, so accounts with numerous incoming paths got a high score. Observe that for popular accounts, TwitterRank provides the best results. Indeed most of large accounts are labeled with several topics. While TwitterRank score relies on the account popularity and on the presence or not of a label for an account (whatever the number of labels it has), TR score considers for its authority score the number of incoming edges labeled with a given topic. But the more labels an account has, the lower authority score for a given topic it may have. Oppositely an account with a low in-degree rarely has several labels. Our approach that also considers semantic similarity between topics on edges is

then particularly efficient. With the DBLP dataset, authors who belong to the 10% less cited are more likely retrieved than with the Twitter dataset for Katz and TR due to the higher density of the graph. However TwitterRank based on the popularity fails to retrieve these authors. Even for the 10% most popular authors, TwitterRank does not achieve the good results obtained for the Twitter datasets, due to a different distribution of the in-degree. While the 10% most followed accounts in Twitter include few extremely popular accounts and some moderately popular, the 10% most followed authors in DBLP consist in a more uniform dataset regarding the in-degree.

Figure 8: Recall w.r.t. popularity

Since the distribution of edge topics is very biased we also study the impact of the popularity of the topic on the recommendations. Results are depicted in Figure 9 for topics **social**, **leisure** and **technology**. Two main conclusions are underlined with this experiment. First, the less popular an account is, the better accuracy for our recommendations we get. So for an infrequent topic like **social** we get a recall-at-10 for TR, Katz and TwitterRank of respectively 0.959, 0.751 and 0.253. Oppositely for the popular topic **technology** we get respectively 0.462, 0.424 and 0.09. Indeed for a popular topic many accounts may be found in a close and connected neighborhood of the account we want to recommend, possibly with a higher score than for the account formerly linked by the removed edge. Second we observe that TR which considers the semantic similarity between topics always outperforms other strategies.

Figure 9: Recall w.r.t. topic popularity

However this experiment does not highlight the quality of the recommendations performed by each algorithm but only the ability to retrieve a removed link between two followers

(link prediction). To estimate the quality of the recommendations we rely on a user validation.

User Validation Task.

In order to evaluate the relevance of the generated recommendations, we conducted a user validation task on 54 IT users (undergraduate, postgraduate and PhD students, and academics) from which 46% are regular *Twitter* users. We set up an on-line blind test where we ask users to rate the relevance of a set of recommendations for a given topic on a scale from 1 (low relevance) to 5 (high relevance). A recommendation set consists in the top-3 recommendations given by Katz, TR and TwitterRank, so 9 recommended accounts for topics **Technology**, **Social** and **Leisure**. On the interface the recommendation list is shuffled, and for each recommendation we display a sample of 5 randomly chosen tweets from the corresponding account.

Figure 10: Relevance scores (user validation Twitter)

Figure 10 presents the results of our user validation. We observed that the user during the validation usually mark with the average 2 or 3 value all accounts when he was doubtful about the relevance or not of an account what happened usually when tweets were neutral, unclear, or when they required some knowledges about a given topic (*e.g.* few European people know who is Tom Brady so can not assert this tweet is about the **leisure** topic). So scores greater than value 3 are significant since they means users really observe the relevance of an account.

From this experiment we conclude that on average TR and TwitterRank provide more relevant recommendations according to the topic searched. However according to the popularity of the topics (see Figure 3) we have very different results. The **social** topic gave more homogeneous results with a score between 2.7 for TwitterRank, 2.8 for Katz and 2.9 for TR. The reason for this result is that posts published by these accounts are generally difficult to classify since they mix social and health, or social and politics for instance. Oppositely topics like **leisure** or **technology** are less ambiguous. For these topics, we see that TR and TwitterRank outperform Katz, which was expected since these two approaches consider the content published for their recommendation scores, unlike Katz. While TwitterRank generally recommends accounts with a large number of followers, TR can also recommend smaller account but more specialized, which results in a better relevance score for topic with a medium popularity like **leisure**, when TwitterRank is slightly better for the most popular topic **technology**.

We also conduct a user validation for the DBLP dataset. We build a list with the top-3 recommendations returned

by each method for researchers from our lab. Observe they belong to different areas (IR, DB, OR, network, software engineering, etc). To illustrate how the different methods may help to discover relevant authors we limit to 100 the number of citations of the authors returned by each algorithm (so we avoid to propose very popular and obvious authors). We propose to each researcher the randomized list with the 9 authors retrieved based on his DBLP entry. He marks each proposal between 1 and 5 according to the relevance of the proposal (*i.e.* the proposed author could have been cited regarding the past publications done by the researcher). We collect 47 answers and results are presented in Table 3.

	Katz	TR	TWR
average mark	2.38	2.47	1.51
# 4 and 5-mark	46	47	11
best answer (%)	0.38	0.50	0.12

Table 3: User validation (DBLP)

The first row shows that both Katz and TR outperform TwitterRank on this dataset. The second row shows that around a third of the recommendations proposed by Katz and TR are considered particularly relevant by our panel (4 or 5-mark) while only 8% are so-considered with TwitterRank. A first rationale is that papers we cite, including papers from co-authors, often cite the same relevant articles within a topically-closed research community. The importance of the semantics on edge is less than with Twitter since researchers, whatever the number of articles they published, cite/are cited by mainly researchers from their community. This explains the close score for Katz and TR. The important role of the popularity in TwitterRank explains its poor results in this context since it proposed popular authors even when there exists a small number of paths between the query author and them. Last row confirms the quality of our recommendations since TR presents for 50% of the tests the best top-3 recommendations, when Katz and TwitterRank achieve respectively 38% and 12%.

5.4 Approximate computations

We perform a set of experiments to illustrate the benefits of the landmark-based approximate computations. Since results may be highly related to the choice for the landmarks selection, as underlined in [22], we decided to implement and compare recommendations based on 11 different landmark selection strategies presented in Table 4.

Size and building time of the landmark index. A first experiment highlights the important time discrepancy for the landmark selection algorithms (see Table 5). Obviously random selections of the landmarks like RANDOM, BTW-FOL and BTW-PUB are the fastest strategies (around 2ms per landmark), while strategies based on the centrality property are 5 orders of magnitude slower (around 17h) due to $O(N^2 \cdot \log N + NE)$ centrality complexity (with Johnson’s algorithm). Table 5 also illustrates that the recommendation computation for a given landmark is almost independent of the landmarks selection strategy (between 12 and 15 mns), which means that convergence is achieved in a similar number of steps after exploring a similar number of paths.

Comparison of the landmark selection strategies for recommendations. We evaluate our approximate approach

Algorithm	Description
RANDOM	Draw landmarks with a uniform distribution
FOLLOW	Draw landmarks with a probability depending on their # of followers
PUBLISH	Draw landmarks with a probability depending on their # of publishers
IN-DEG	Landmarks are nodes with highest in-degree
BTW-FOL	Draw landmarks among nodes with # of followers in [min_follow, max_follow]
OUT-DEG	Landmarks are nodes with highest out-degree
BTW-PUB	Draw landmarks among nodes with # of publishers in [min_publis, max_publish]
CENTRAL	Select landmarks that are reachable at a given distance from most of chosen seed nodes
OUT-CEN	Select the landmarks based on the number of different output seeds that they cover
COMBINE	Weighted combination between the CENTRAL and OUT-CEN
COMBINE2	Weighted combination between the BTW-FOL and BTW-PUB

Table 4: Landmarks selection algorithms proposed

Strategy	landmarks	
	select. (ms)	comput. (s)
RANDOM	2.4	756.7
FOLLOW	3,712.8	877.3
PUBLISH	3,614.7	868.6
IN-DEG	459.6	854.3
BTW-FOL	2.4	735.1
OUT-DEG	1,815.7	918.6
BTW-PUB	1.7	822.7
CENTRAL	61,060.2	807.8
OUT-CEN	66,862.3	816.5
COMBINE	130,461.8	818.2
COMBINE2	2.45	805.6

Table 5: Determining landmark w.r.t. strategies

presented in Section 4. We perform a BFS at depth 2 from a query node and combine scores with the ones of the landmarks encountered. (see Algorithm 2). Then we compare the recommendations retrieved with the ones provided by the exact computation with convergence. Average results for 100 landmarks are reported in Table 6.

Strategy	#Lnd	time in s (gain)	L10	L100	L1000
RANDOM	2.9	0.93 (338)	0.130	0.124	0.125
FOLLOW	17.5	0.83 (379)	0.377	0.140	0.096
PUBLISH	11.7	0.58 (539)	0.349	0.136	0.100
IN-DEG	58.9	0.84 (373)	0.523	0.149	0.066
BTW-FOL	3.5	0.55 (577)	0.061	0.059	0.058
OUT-DEG	6.2	0.81 (388)	0.518	0.147	0.064
BTW-PUB	2.9	0.54 (585)	0.129	0.127	0.123
CENTRAL	5.3	0.76 (414)	0.134	0.123	0.125
OUT-CEN	4.4	0.74 (425)	0.172	0.131	0.121
COMBINE	4.2	0.71 (443)	0.180	0.125	0.118
COMBINE2	3.7	0.54 (584)	0.129	0.126	0.124

Table 6: Comparison of the landmark selection strategies

First we observe that the number of landmarks encountered during the BFS at distance 2 differs from one strategy to another and ranges from 2.9 on average for the RANDOM strategy to 58.9 for IN-DEG. Centrality approaches lead to less landmarks encountered since they select landmarks among nodes which connect connected subgraphs and a two-hop BFS is more unlikely to visit several connected subgraphs. We notice that the processing time does not depend

on the number of landmarks found, what seems counterintuitive since more landmarks means more computations (score combinations) to perform. The rationale is that we perform pruning when we encounter a landmark during the BFS, to avoid considering twice paths from the BFS which pass through a landmark. Since the recommendation computation is dominated by the BFS exploration and computation, this pruning largely reduces the whole processing time. A second important result is that our approximate computation allows to get a *2-3 order of magnitude gain compared to the exact computation*. Finally observe that a strategy which allows to find more landmarks is more tolerant to a landmark departure or to a landmark with outdated recommendation values.

Finally to validate the quality of the approximate computation we report the average Kendall Tau distance between the approximate computation and the exact computation obtained at convergence when a landmark stores respectively the top-10, top-100 or top-1000 recommendations for all topics (see last 3 columns of Table 6). Keeping 1000 recommendations for the landmarks at the pre-processing allows to reach a Kendall Tau distance between 0.06 and 0.13 for the top-100 recommended accounts for a node at query time. Keeping a top-10 at landmarks leads to a higher Kendall Tau distance since a landmark may update at most 10 scores from the top-10 built at distance 2 from the BFS. Consequently an account which is ranked at the 11th place for two landmarks is not kept as a recommendation whereas its aggregate score may be higher than accounts kept as recommendations. Remark that even when storing the top-1000 for each topic, the landmarks recommendations can easily fit in memory since they require 1.4MB storage each.

6. CONCLUSION

We present the TR recommendation score which combines topology and semantic information regarding the user interest. To face prohibitive computations with very large graphs, we propose a landmark-based approach which requires a pre-computation step for a small set of identified nodes and achieves a 2-3 order of magnitude gain compare to the exact computation. The experiments and user validation show that TR outperforms other algorithms. As future work we intend to study updating strategies since many following links have a short lifespan. This graph dynamicity may impact the scores stored by the landmarks. Moreover we made the choice to handle the recommendation task in a centralized manner motivated by the current social media architectures like *Twitter Who-to-Follow* service hosted on a single server. However, with the continuous increase of the social graph sizes, distribution strategies must be considered in the future. Regarding our approach, distribution implies to split the graph by taking into account connectivity, but also to perform landmark selections and distributions that allow a node to evaluate the recommendation scores “locally” minimizing network transfer costs.

Slowing the Firehose: Multi-Dimensional Diversity on Social Post Streams

Shiwen Cheng, Marek Chrobak, Vagelis Hristidis
Department of Computer Science & Engineering
University of California, Riverside, California, USA
{schen064, marek, vagelis}@cs.ucr.edu

ABSTRACT

Web 2.0 users conveniently consume content through subscribing to content generators such as Twitter users or news agencies. However, given the number of subscriptions and the rate of the subscription streams, users suffer from the information overload problem. To address this issue, we propose a novel and flexible diversification paradigm to prune redundant posts from a collection of streams. A key novelty of our diversification model is that it holistically incorporates three important dimensions of social posts, namely content, time and author. We show how different applications, such as microblogging, news or bibliographic services, require different settings for these three dimensions. Further, each dimension poses unique performance challenges towards scaling the diversification model for many users and many high-throughput streams. We show that hash-based content distance measures and graph-based author distance measures are both effective and efficient for social posts. We propose scalable real-time stream processing algorithms leveraging efficient indexes that input a social post stream and output a diversified version of the stream, diversified across all three dimensions. Next, we show how these techniques can be extended to serve multiple users by appropriately reusing indexing and computation where possible. Through extensive experiments on real Twitter data, we show that our diversification model is effective and our solutions are scalable. We show that different algorithms perform best for different application settings.

1. INTRODUCTION

Tremendous amounts of online social data are generated every day. For instance, Twitter has reported over 280 million monthly active users in its microblogging service and 500 million Tweets posted per day¹. One common way to consume social data is through implicit or explicit subscription. For example, almost all news agencies offer RSS feeds for people to subscribe. Google Scholar continuously recommends new publications to its users based on a user's profile and publication history. In a microblogging system like Twitter, one can subscribe to other users' posts by following them.

¹<https://about.twitter.com/company>

All posts matching a user's subscriptions are typically displayed in a convenient central place, such as the user's timeline in Twitter or Facebook. These timelines are updated in real time. A key challenge is that a user could be easily overwhelmed by the number of posts in the timeline, especially if the user is subscribed to many post producers. Further, a user's timeline often contains lots of posts that carry no new information with respect to other similar posts. This data overload issue also happens in other applications with smaller data throughput such as news and research papers. For instance, it has been shown that a primary care physician should read hundreds of medical publications per day to keep up with the medical literature [2].

To alleviate the data overload problem, in this paper we propose a novel way to efficiently and effectively diversify social post streams by pruning redundant posts. By social post streams we mean a broad class of content generated by services where each post, in addition to its textual content, has a unique author and a unique timestamp, and where authors are associated through various social relationships. For instance, in Google Scholar authors are connected by relations such as co-authorship or overlapping research interests. In microblogging sites users are connected by follower/followee relations.

Given a stream consisting of all the posts from a user's subscriptions, our goal is to output in real-time a subset of the stream in which (i) all posts are dissimilar to each other and (ii) any post in the whole stream will be either included or *covered* by a post in the sub-stream. A post covers another post if the two posts are similar in all three similarity dimensions: (a) content, (b) time and (c) author.

Two posts have similar *content* if their text components are similar. Intuitively, all other dimensions being equal, users want to avoid seeing two posts with very similar content. Similarly, the *timestamp* distance of two posts is important in social post diversification. Two posts that have similar content but are far away in terms of post time, may both be of interest to the user. Note that time is widely used for diversifying search results in microblogging systems [10, 14, 4].

The *author* similarity is a more subtle dimension that to the best of our knowledge has not been used before for computing diversity in social media. For example, CNN and Fox News, which both have official Twitter accounts, are dissimilar to each other because they generally have different political views. We compute the distance between two authors through their social connections. In particular, we compare the sets of friends (or followers in the case of Twitter) of the two authors, which has been shown to be a good author similarity measure in social networks [21, 9].

Challenges: To summarize, in our model two posts are redundant with respect to each other if they are similar in all of the three

dimensions. It is challenging to apply the proposed diversification model in a large scale social service with high posts throughput. First, we must efficiently compare the content of a new post to the content of all previous posts (within a time window). For this, we apply Hash-based techniques to measure the content similarity between social posts. Hash-based techniques have been applied before to Web documents [11], but not to social posts, which are generally shorter and may heavily rely on abbreviations or URLs.

Second, handling the author dimension is challenging. A naive approach is to check if the author of each new post is similar to the author of each existing post (within a time window). However, we show that depending on the setting (similarity thresholds across the three dimensions), a different indexing data structure is more efficient to achieve real-time posts processing.

Third, the three diversity dimensions offer an opportunity to use the results of the one dimension to prune the work needed for the other dimension. For instance, if a reader knows that posts P_1 and P_2 have high content similarity, then she doesn't need to check if their authors or time are similar.

Fourth, if we move from one user to many users, where each user has a collection of subscriptions, the challenge is how to reuse the computation performed for diversifying one user's stream to diversify streams of other users. We show that we can reuse computation across users only if their shared subscriptions meet a strict condition.

Previous work on diversity: There has been much work on diversifying results for documents [15, 1, 3], social posts [10, 14, 4] and database records [5, 6]. However, none of these works can be applied to our setting where: (i) data is streaming and an instant decision must be made on whether a post should be pushed to the user, and (ii) a multi-dimensional diversity model is adopted. In contrast, most previous works focus on the search setting, where a user submits a query and the set of results must be diversified based on content, including work on social posts [10, 14].

The problem studied in this paper is also fundamentally different from previous work on stream summarization [20, 18, 16, 23], because: (i) we do not aim to generate an aggregation of documents, but instead select a subset of posts, and (ii) we define strict coverage constraints to guarantee that not even one uncovered posts is missed.

Contributions: In this paper, we make following contributions:

- We propose a new paradigm to define diversity on social posts, by incorporating three important dimensions – content, time and author – and we define corresponding optimization problems (Section 2).
- We study how content similarity can be efficiently applied to social posts, which are generally short and contain abbreviations (Section 3).
- We propose efficient data structures and algorithms to solve the social posts stream diversification problem (Section 4).
- We show how the single-user algorithm can be extended to handle many users, by reusing computation across users (Section 5).
- We perform a comprehensive experimental evaluation, where we focus on microblogging data, which poses the most serious scalability challenges. We show how different algorithms perform better for different diversity needs (Section 6).

Section 7 reviews related work. We conclude in Section 8.

2. FRAMEWORK AND PROBLEM DEFINITION

Let P represent a stream (ordered set) of social posts. Each post P_i in P has an author $author(P_i)$, textual content $text(P_i)$ and a timestamp $time(P_i)$ (also referred as t_i). We define the distance measures across the three diversity dimensions as follows.

- **Content Distance.** We represent the content distance between two posts P_i and P_j as $dist_c(P_i, P_j)$. Cosine similarity is a possible way to define the distance, but for efficiency purposes we employ the hash-based simhash measure as explained in Section 3, where we show that simhash is effective for social posts.
- **Time Distance.** The time distance between two posts P_i and P_j is denoted as $dist_t(P_i, P_j) = |t_i - t_j|$.
- **Author Distance.** We denote the author distance between P_i and P_j as $dist_a(P_i, P_j)$. For social data, we define the similarity between two authors as the cosine similarity between their friends' vectors, which has been successfully used in previous work to measure the user similarity in Twitter [21, 9]. The author distance is $(1 - similarity)$. For other domains other distance measures may be more appropriate.

Next, we define the coverage semantics between posts.

Definition 1. (Post Coverage) Given a content diversity threshold λ_c , a time diversity threshold λ_t and an author diversity threshold λ_a , two social posts P_i and P_j cover each other if:

- $dist_c(P_i, P_j) \leq \lambda_c$ and
- $dist_t(P_i, P_j) \leq \lambda_t$ and
- $dist_a(P_i, P_j) \leq \lambda_a$.

Note that the coverage semantics between two posts is symmetric. The three thresholds may vary according to the characteristics of a social system as we discuss below. The primary focus of this paper is to study the efficient processing of a posts stream and not to set these threshold values.

We next define the Social Post Stream Diversification (SPSD) problem.

Problem 1 [Social Post Stream Diversification (SPSD)] Given a social post stream P , and diversity thresholds λ_c , λ_t and λ_a , compute a sub-stream of posts $Z \subseteq P$ that covers P , that is, $\forall P_i \in P \exists P_j \in Z$, such that P_j covers P_i .

Note we have to compute Z in *real-time*, i.e., immediately decide whether a post P_i should be included in Z at its arrival. That is, we cannot first view the whole stream and then decide which posts should be included in the substream.

In SPSPD, there is a single user who consumes the stream and many authors who generate the posts of the stream (a user may also be an author and vice versa). That is, a solution to SPSPD should be deployed for each user, for example, as part of the Twitter app of a user. On the other hand, a social network service would rather have a central diversification engine that diversifies the posts for each of its users, so that no client side post processing is required. We refer to this version of SPSPD as Multiple-Users SPSPD (M-SPSPD). Another difference between SPSPD and M-SPSPD is that in SPSPD we can easily support user customized diversity thresholds. Figure 1 shows how SPSPD and M-SPSPD differ in terms of the setting and deployment.

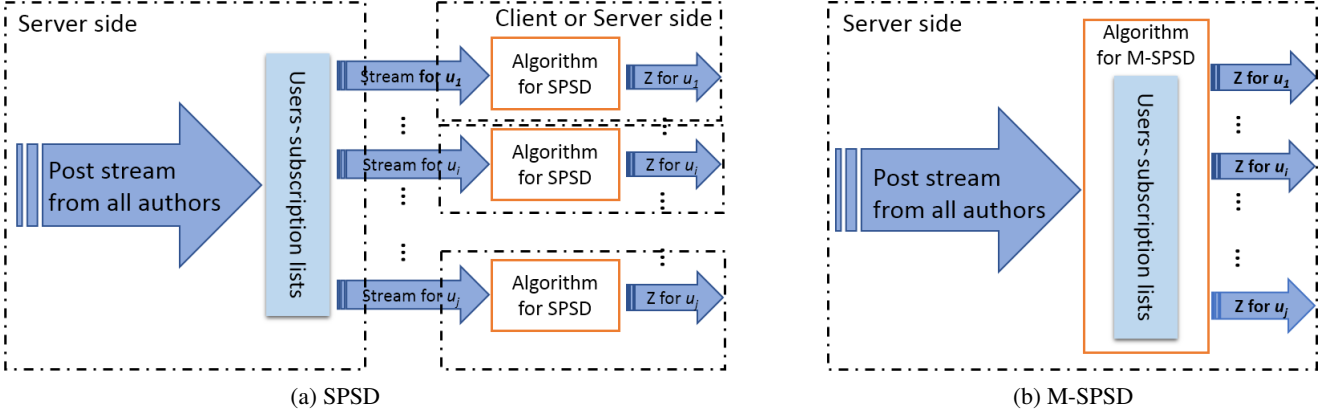

Figure 1: Settings of SPDP and M-SPDP.

Problem 2 [Multiple-Users Social Post Stream Diversification (M-SPSD)] Given a social post stream P , diversity thresholds λ_c , λ_t and λ_a , and a set of users where each user is subscribed to a subset of the authors, compute a diversified sub-stream for each user.

3. CONTENT DISTANCE ESTIMATION FOR MICROBLOGGING POSTS

Among the three diversity dimensions, the content distance is the most expensive to compute, because it must be computed for each new post. This is especially true given our real-time decision semantics described above. In contrast, the author similarity between each pair of authors may be precomputed (e.g., once every week), as it changes slowly over time. For that reason, we cannot afford to use traditional content similarity measures such as cosine similarity. Instead, we turn to hash-based distance measures. In this section we present the details of the employed content distance technique along with an analysis of its effectiveness for microblogging data.

We define the content distance between two posts P_i and P_j as the Hamming distance of their SimHash [17] fingerprints. Previous work has applied SimHash on web documents [11] and showed that it is efficient and effective. We represent the SimHash of $text(P_i)$ as S_i , which is a 64-bit fingerprint. The Hamming distance of two SimHash fingerprints is the number of different bits between them. According to the experimental analysis in [19], the cosine distance between two texts positively correlates to the Hamming distance of their corresponding SimHash fingerprints.

Distribution of SimHash distances in Twitter

First, we study the distribution of SimHash distances on Twitter data. We collected a dataset of 200 thousand tweets from the Twitter Streaming API, which returns a stream of randomly selected substream of Twitter ([12] showed that the stream is not exactly random but this is not too important for our problem). The distribution of the Hamming distances for these tweets is depicted in Figure 2, which shows a perfect normal distribution with mean value 32, as expected, and with most of the distances between 24 to 40.

User Study

To further evaluate the effectiveness of SimHash for social posts, we conducted a user study to learn the relationship between the SimHash distance between two posts and the perceived dissimilarity between the posts. A second goal of the study is to learn what is a good SimHash distance threshold (e.g., a threshold of 3 bits was

Figure 2: Hamming distance distribution

chosen to define redundant Web pages [11]) and if any preprocessing of the tweet text (e.g., expand shortened URLs) may improve the effectiveness of SimHash.

Setup and Methods: In particular, we collected a dataset of 2000 pairs of tweets randomly selected from the 200,000 tweets returned by the Twitter Streaming API, with SimHash distances between 3 and 22 – 100 tweets from each distance value. We chose 3 to 22 because this is the range where we expect to find posts that are very similar (redundant with respect to each other). This range choice is supported by our results below. We recruited 12 undergraduate and graduate students.

We evenly divided these 2000 pairs into 4 groups and distributed them to the 12 students for labeling. The author and timestamp of the posts are hidden. Some examples of these pairs are shown in Table 1. Each group of tweets is labeled by 3 students. The students were asked to mark whether the two tweets in a pair are redundant with respect to each other.

To help the users more accurately label the similarity between two posts, we showed the expanded URL (instead of the shortened one shown in Table 1). We used a majority vote, that is, if at least 2 out of the 3 students labelled a pair as redundant, we labelled the pair as near-duplicates.

Results: Out of the 2000 pairs, the users marked 949 pairs as redundant. Figure 3 shows the precision and recall achieved by various SimHash distance values. For each Hamming distance h , the precision is defined as the fraction of pairs with Hamming distance no more than h that are true near-duplicates. Recall is the

fraction of the total number of near-duplicate pairs that are detected with Hamming distance at most h . This graph shows that SimHash distance is an effective measure to identify similar posts.

Figure 3: Precision and Recall for Hamming distance. SimHash fingerprints are generated from raw texts of tweets

Next, we study if various text preprocessing methods may improve the precision or recall of SimHash distance measure for microblogs. We first normalize the text by (a) changing all text to lowercase, (b) removing extra white spaces between words, and (c) removing non-alphanumeric characters (such as *, -, +, /, etc.). Figure 4 plots the precision and recall after we apply the normalization. We see that this graph achieves higher precision and recall values than the original analysis in Figure 3. We also see that the two lines cross for $distance = 18$, which achieves precision = 0.96 and recall = 0.95. Hence, we use $\lambda_c = 18$ as the default content distance threshold in the experiments in Section 6.

We also tried other methods of text preprocessing such as expanding shortened URLs (URLs in tweets are shortened by Twitter), varying the weights of user mentions and hashtags (by creating artificial copies), and expanding abbreviations. However, these methods had no significant impact to the precision and recall.

For completeness, we compared the effectiveness of SimHash to that of cosine similarity (which is much slower as discussed above) in terms of detecting posts with near-duplicate content (redundant). We tried different cosine threshold values and found that the precision and recall lines across at cosine similarity 0.7, where all posts with cosine similarity above 0.7 are marked as redundant. This achieves precision and recall of 0.96 and 0.95 respectively, which is the same as what we achieved using SimHash above. This means that, for detecting near-duplicate in our dataset, SimHash achieves effectiveness similar to cosine similarity. Hence, given the time performance advantage of SimHash, it is the best choice for our problem.

The high threshold value of $\lambda_c = 18$ for SimHash precludes the

Figure 4: Precision and Recall for Hamming distance. SimHash fingerprints are generated from normalized texts of tweets

use of the efficient SimHash index proposed in [11] which relies on building several copies of the SimHash values table for several permutations of the bits, since the number of these copies is exponential in λ_c (which was only 3 in [11]). Hence, as we discuss in Section 4, other indexing and searching techniques are required.

4. ALGORITHMS FOR SPSP

In this section, we describe our algorithmic solutions for the SPSP problem. As explained earlier in Section 3, due to the high Hamming distance threshold we are unable to use existing SimHash indexing techniques, and we must rely on comparing the SimHash value of each new post with those of all the previous ones, leading inevitably to linear time complexity per post in the worst case. We reduce the number of these comparisons by leveraging the other two dimensions, time and author. We first discuss how we handle time diversity, which is simpler, and then we present various approaches for handling author diversity.

Handling Time Diversity. According to the diversity model, at the arrival of a post P_i it can only be covered by the previous posts within a λ_t time distance. Thus, it is sufficient to store only the posts from previous λ_t time in memory for checking the coverage of a new post. One possible implementation is that we could store the posts in a circular array. We track two post indices for the oldest post within a λ_t distance to current time (a) and the most recent post (b). At the arrival of each post P_i , we compare it to the posts from most recent post to the oldest (i.e., from index b to a). If we encounter a post P_j with $t_i - t_j > \lambda_t$, we update a to be index of the post right after P_j . And we insert a non-redundant post to the array with index $(b + 1)$ and update $b = b + 1$.

Now that we have discussed how to handle time diversity, we focus on the author diversity among the posts in the last λ_t time units. The author similarity relations between all authors form an

author similarity graph G , which as we discussed above may be periodically precomputed. There is an edge between two authors in G if their distance is below the threshold λ_a . For each user u_i who subscribes to a set A of authors, we define G_i as the subgraph of G that contains all the A authors and the edges among them. In this section, we assume there is only one user (hence, one G_i) and in Section 5 we assume multiple users (and G_i 's).

4.1 UniBin

Our first method to solve SPSPD, which we refer as *UniBin*, works as follows: At the arrival of each post P_i in P , we sequentially (from the most recent post to the older ones) compare P_i to each post in the past λ_t time range in the diversified sub-stream Z . For each post P_j , we check whether P_j meets both: (1) Hamming distance between S_i and S_j (SimHash fingerprints of P_i and P_j , respectively) $\leq \lambda_c$, and (2) $dist_a(P_i, P_j) \leq \lambda_a$, which can be achieved by checking whether $author(P_i)$ and $author(P_j)$ are the same or neighbors in G . If no post from the past λ_t time range meets the above two conditions (i.e., P_i is not covered by Z), then we add P_i to Z . Otherwise we do not include P_i in Z .

We denote this method as **UniBin** indicating that the posts from all authors are stored in a single *post bin* (e.g., a circular array as described earlier). We illustrate UniBin with an example. In Figure 5a, each node represents an author. Two authors are connected by an edge if they are similar to each other (i.e., the author distance $\leq \lambda_a$). Figure 5b shows the posts from these authors with post distance information in terms of all three diversity dimensions.

We show the update of a post bin for UniBin in Figure 6a. When P_1 arrives, there is no posts in the bin yet. Thus P_1 is not covered hence is added to the bin. P_2 is also added as it is not covered by P_1 (the Hamming distance between S_1 and S_2 , $dist_c(P_1, P_2)$, is larger than the threshold λ_c). For P_3 , the algorithm first compares it to P_2 which does not cover P_3 (because $dist_c(P_2, P_3) > \lambda_c$). However, it is covered by P_1 because in all three diversity dimensions they are within the distance thresholds (or above similarity threshold). Thus, P_3 is not added. So forth, P_4 is not covered by either P_1 and P_2 and is included in the bin. However, we note that P_4 and P_3 cover each other. Finally, P_5 is covered by P_4 .

4.2 NeighborBin

UniBin has to compare a new post (both its author and content SimHash) to all posts in the last λ_t time units. This aggregated time may be considerable given the high frequency of posts, even if the author similarity graph G_i and the post bin are maintained in memory.

To improve this, we partition the posts by their authors such that for a new post P_i we only check its coverage by comparing with the posts from $author(P_i)$ or from $author(P_i)$'s similar authors. Specifically, we create a post bin for each author and when a new post P_i comes, the algorithm sequentially checks posts in the bin identified by $author(P_i)$ but not other posts. However, we must note that posts from the authors that are neighbors of $author(P_i)$ in G_i can potentially cover P_i . Hence, the post bin of an author also includes the posts of similar authors (neighbors in G_i). Thus, we add P_i to all bins of $author(P_i)$'s neighbors in addition to the bin of $author(P_i)$, if P_i is detected as a non-redundant post. We denote this method as **NeighborBin**.

Figure 6b depicts the execution of NeighborBin for the data shown in Figure 5. P_1 is added not only to the bin of its author a1, but also to the bins of a2 and a3, because they are neighbors of a1, as shown in Figure 5a. To check the coverage of P_2 , only the post bin of a2 is accessed where P_1 does not cover P_2 . After that, P_2 is also added to the post bins of a1, a2 and a3. NeighborBin checks the

coverage of P_3 by iterating posts in the bin of a3 where P_1 covers P_3 . When P_4 comes, a4's post bin is blank and thus P_4 is added to the post bins of a3 and a4 without incurring any post comparisons. Finally, P_5 is detected as redundant by checking the bin of a3 ($author(P_5) = a3$) where P_4 covers P_5 .

4.3 CliqueBin

In NeighborBin, we index the posts by author aiming to reduce the pairwise post comparisons. But the tradeoff is memory consumption: we have multiple copies of a post in different authors' post bins.

To reduce the overhead on memory consumption incurred by NeighborBin, we identify groups (cliques) of authors that are similar to each other and assign a single bin to them, such that a post generated by any of these authors is only stored in that bin. Specifically we find a *clique edge cover* of G_i , that is a collection of cliques whose union contains all edges of G_i . We maintain a post bin per clique (e.g., a map from clique ID to a list of posts). Only the posts from authors in a same clique as $author(P_i)$ can possibly cover post P_i . Thus, at the arrival of post P_i , we check whether it is covered by sequentially comparing it to the posts from only the cliques that contain $author(P_i)$. Thus a post P_i in Z is stored once for every clique that contains $author(P_i)$ – instead of once for each neighbor of $author(P_i)$ in NeighborBin. Note that this approach guarantees that the coverage requirement for posts is satisfied: when a new post P_i authored by a_j appears, and P_i is not similar to earlier posts of a_j or its neighbors then P_i will be added to the cliques involving a_j , because a_j 's edges are covered by the cliques.

Considering the space consumption, our objective should be to minimize the sum of the sizes of cliques, i.e., the average number of cliques per author is minimized and thus number of copies per post is reduced. This is an NP-hard problem, and hence we have decided to use a simple greedy heuristic. It starts by picking an edge in G_i to form an initial clique. Then it extends the clique by adding nodes that are neighbors to all the nodes in the clique. When there is no such node, the clique is saved and the algorithm picks another edge not yet included in any found cliques and repeats the above process. We stop when all edges are covered.

Upon a new post P_i , we use a hashmap (Author2Cliques) to get all the cliques that contains $author(P_i)$, and then we check the posts in the corresponding bins. Recall that NeighborBin and UniBin load the author similarity graph G_i in memory. We can make the same assumption that Author2Cliques is loaded in memory for applying CliqueBin. Similar to the computation of author similarity graph, we assume the clique partition of G_i and the Author2Cliques mapping are computed offline. We denote this algorithm as **CliqueBin**.

The update of a post bin by CliqueBin is depicted in Figure 6c. Cliques C0 and C1 together cover all the edges in the graph. We can see that P_1 is only stored once in C0's bin (because a1 is in C0) instead of saving 3 copies in NeighborBin as Figure 6b. The same applies to P_2 . Since a3 is in both C0 and C1, during the processing of P_3 CliqueBin may check both bins of C0 and C1. P_4 will only be compared with the bin of C1 because a4 belongs to only C1. Again, CliqueBin checks the coverage of P_5 by iterating both bins of C0 and C1. This example illustrates how CliqueBin can reduce space requirements compared to NeighborBin.

We note that in some cases CliqueBin may have to do a larger number of pairwise post comparisons than NeighborBin. Suppose that after P_5 in the above example author a3 posts P_6 and then author a4 posts P_7 . If P_6 and P_7 are not redundant to any other posts, then P_6 should be added to all four post bins in NeighborBin, and

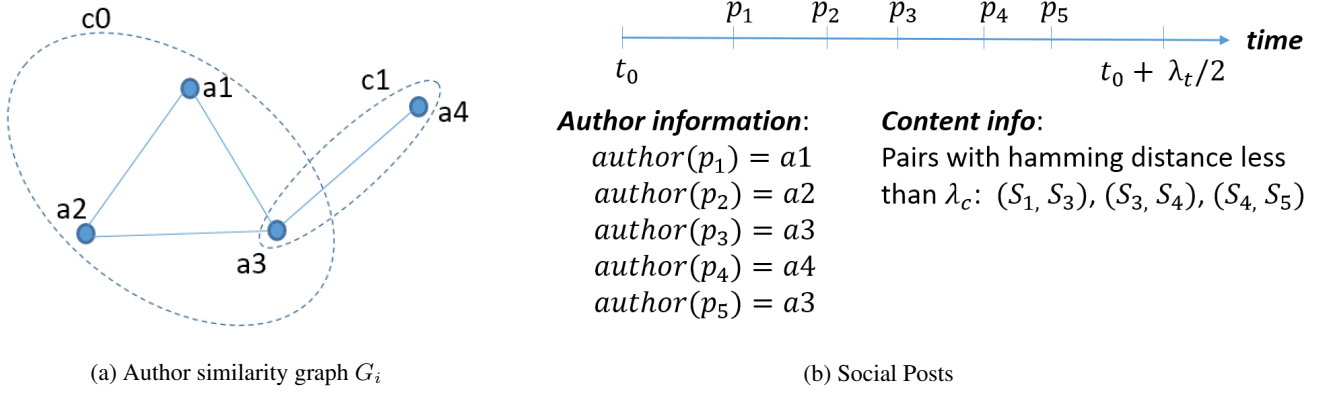

Figure 5: Example of author similarity graph and posts

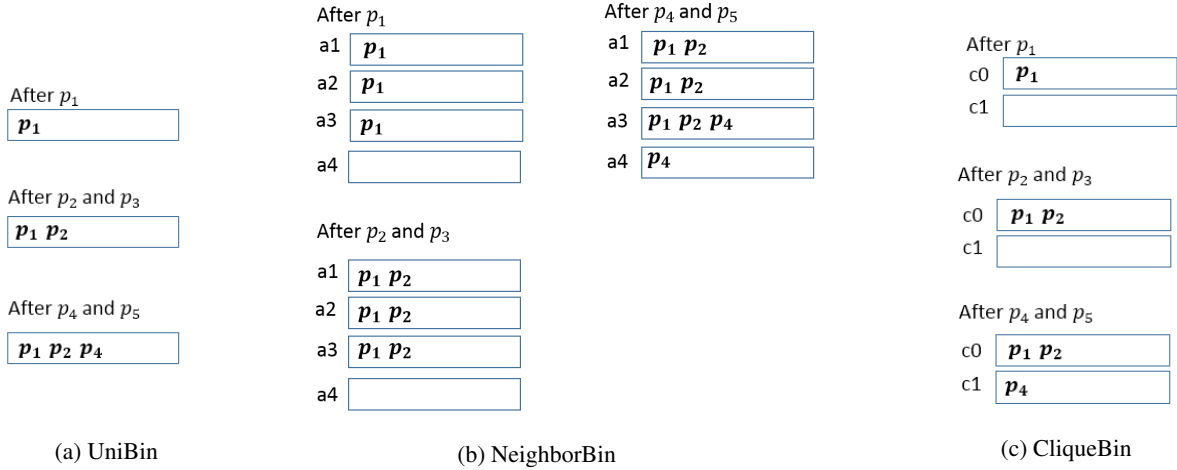

Figure 6: Running example for the three algorithms for SPSP.

to both post bins in CliqueBin. For P_7 , NeighborBin only accesses the bin of $a4$ and thus only needs to do two comparisons (with P_4 and P_6). In contrast, CliqueBin has to do 5 comparisons: with P_1, P_2, P_4 and twice with P_6 (once in post bin of each clique). We study this experimentally in Section 6.

4.4 Performance Analysis

In this section we show an estimate of the time and space complexity of our algorithms, attempting to capture their performance on realistic data, rather than the worst-case performance. Rigorous derivation of such estimates is challenging, because the behavior of these algorithms heavily depends on the specifics of the data sets, including the topology of the social network. Instead, we provide informal derivations based on several reasonable assumptions about the data set and the graph's topology.

Suppose there are m subscribed authors, and the total number of posts from these m authors in a λ_t time range is n . We assume a ratio of r (≤ 1) posts left after diversification, that is, $r \cdot n$ non-redundant posts per λ_t time. We also assume that the each author generates the same number of $\frac{n}{m}$ posts with $\frac{r \cdot n}{m}$ left after diversification. Further we assume in the author similarity graph, each author has d neighbors and is in c ($\leq d$) cliques. We denote s as the average number of authors in a clique.

Note that cliques may have overlaps. If we define q as the num-

ber of edges in G over the total number of edges in c cliques from G , we have $\frac{m \cdot c}{s} = \frac{m \cdot d}{s \cdot (s-1) \cdot q}$, where both sides compute the number of distinct cliques. Thus we can expect $c \cdot (s-1) \cdot q = d$ with $0 \leq q \leq 1$.

Recall that UniBin puts posts from all authors in Z into a single post bin. Thus, the total bin size is $r \cdot n$ in UniBin. Each new post is sequentially compared to each post in the bin and thus the number of post comparisons per new post is $r \cdot n$. Each non-redundant post incurs one insertion into the bin.

NeighborBin maintains a set of per-author bins with each bin storing posts from an author and her similar authors. Roughly, each per-author bin stores $\frac{d+1}{m} \cdot r \cdot n$ posts. Thus the total number of post copies stored in memory is $(d+1) \cdot r \cdot n$. At the arrival of a new post P_i , the number of post comparisons made by NeighborBin is $\frac{d+1}{m} \cdot r \cdot n$ (compare P_i to all posts in $author(P_i)$'s post bin). Each non-redundant post incurs a total of $(d+1)$ insertions into the bins.

In CliqueBin, for each non-redundant post P_i we store its c copies: one copy in the bin of each clique containing $author(P_i)$. Thus, the total size of the clique bins is $c \cdot r \cdot n$. CliqueBin compares each new post P_i to posts in the bins of c cliques that contain $author(P_i)$, which leads to a total of $\frac{s \cdot c}{m} \cdot r \cdot n$ comparisons. Each non-redundant post incurs a total of c insertions into the bins.

Table 2 summarizes the performance analysis. We can see that all these results contain the same component $r \cdot n$. Obviously, all

Table 2: Performance estimation of the algorithms for SPSP

	UniBin	NeighborBin	CliqueBin
RAM	$r \cdot n$	$(d+1) \cdot r \cdot n$	$c \cdot r \cdot n$
Comparisons in λ_t	$r \cdot n^2$	$\frac{d+1}{m} \cdot r \cdot n^2$	$\frac{s \cdot c}{m} \cdot r \cdot n^2$
Insertions in λ_t	$r \cdot n$	$(d+1) \cdot r \cdot n$	$c \cdot r \cdot n$

three diversity thresholds effects the ratio of non-redundant post r . The value of n is affected by several factors, such as the frequency of the post stream \mathbf{P} and the setting of time diversity threshold λ_t .

An important factor that affects the performance of the algorithms, especially NeighborBin and CliqueBin, is the topology of the author similarity graph G . In the above estimates, we use parameters d, c, s and m to capture the topology properties. We note that the values of the ratios of d, c, s to m are functions of the author diversity threshold λ_a . Given a set of subscribed authors (i.e., with m fixed), the larger λ_a the denser G is (in terms of the number of edges). Thus, the number of neighbors per author (d) increases with λ_a , which means the performance of NeighborBin will drop if all other settings remain unchanged. We also argue that c and $c \cdot s$ increase with the graph's density, and hence we expect CliqueBin to perform better for smaller λ_a s. In Section 6, we confirm this through experiments on real data set.

In Section 6 we will summarize the use cases for each algorithm based on this theoretical analysis combined with our experimental results.

4.5 Summary

We summarize the characteristics of the three algorithms in Table 3. In terms of data structure, UniBin and NeighborBin need the author similarity graph, while CliqueBin needs the mapping of each author to the set of cliques containing the author. As we mentioned, we assume that all these data structures are maintained in memory.

We can see that UniBin requires the least RAM. NeighborBin reduces the post comparisons compared to UniBin, but has high RAM consumption because it maintains multiple copies of a post. CliqueBin outperforms NeighborBin in terms of RAM consumption, by reducing the number of copies per post (and thus insertions per post), but it incurs more post comparisons. Since CliqueBin still maintains multiple copies of a post, it requires more insertions and higher RAM consumption than UniBin. Also, since CliqueBin does not compare posts from non-similar authors, we expect the number of comparisons in CliqueBin to be lower than in UniBin.

5. ALGORITHMS FOR MULTIPLE-USERS SPSP (M-SPSP)

In this section, we extend our ideas to solving M-SPSP. When we move from applying the diversity model for one user to multiple users, the crucial question is whether it is possible to reuse the computation performed for diversifying one user's stream to diversify the other users' streams.

A simple way to solve M-SPSP is to process the post stream for each user individually. That is, we can apply the algorithm for SPSP on each user's post stream separately. We denote the corresponding algorithms for M-SPSP as **M_UniBin**, **M_NeighborBin** and **M_CliqueBin** respectively, to distinguish them from the algorithms for SPSP. In this section, we present variations of these algorithms to optimize the diversification process by reusing computations for multiple users who share subscriptions.

If two users do not share any common subscriptions, then their

post streams are disjoint and thus the computation of diversifying one's stream cannot be reused for diversifying the other users' post streams. Hence we only consider the cases for optimization when users share the same subset of subscriptions.

Figure 7: Author similarity graphs of two users u_1 and u_2 .

However, we notice several limitations to reusing the diversification computation across multiple users, even if they share some subscriptions. We use examples to illustrate this. Figure 7 shows two users, u_1 and u_2 , sharing a set of subscriptions $\{a_1, a_2, a_4, a_6\}$.

We notice that after diversification u_1 may see a different subset of the posts from a_4 as u_2 . u_2 subscribes to a_5 which is a similar author to a_4 . Thus, it is possible that some posts from a_4 are shown to u_1 but not to u_2 if they are covered by a_5 's posts.

However, the same diversified set of posts from $\{a_1, a_2, a_6\}$ will be shown to u_1 and u_2 . The three authors form a *connected component* (denoted as g_1 in Figure 7) in both G_1 and G_2 . That is, in both G_1 and G_2 there are no other authors similar to any author in $\{a_1, a_2, a_6\}$. Hence, posts from other subscribed authors can not cover the posts from $\{a_1, a_2, a_6\}$. Thus, the diversification processes on the posts from $\{a_1, a_2, a_6\}$ are exactly the same for u_1 and u_2 . This means that we can reuse the data structures and computation across u_1 and u_2 for diversifying the post stream from $\{a_1, a_2, a_6\}$.

Based on these observations, we can optimize the diversification process for multiple users if they subscribe to a same set of authors that form a connected component. We can then consider a post stream (a subset of \mathbf{P}) of each connected component separately, apply the diversification algorithm on it, and then merge the diversified post streams together.

For this, we first process the author similarity graph G_i of each user u_i to compute all connected components of all G_i s. (Since different G_i s may overlap, some nodes may appear in several components.) For each distinct connected component g_i , we run one of the proposed algorithms for SPSP on the post stream by the authors in g_i . User u_i 's post stream consists of the union of the diversified post streams from all connected components in G_i .

For example, as shown in Figure 8b, we can apply the UniBin algorithm for three distinct connected components (g_1, g_2 and g_3), that is, we maintain a single post bin for each of the three components. Then the posts shown to u_1 is the union of the two diversified post streams from g_1 and g_2 . We refer this algorithm as S_UniBin . For comparison, we show the example for M_UniBin in Figure 8a. M_UniBin maintains a post bin for each user separately. To extend NeighborBin, we maintain a per-author post bin for each author in a distinct connected component g_i . To extend CliqueBin, we do the clique partition for each g_i , then maintain a per-clique post bin as described earlier.

We denote the three algorithms with the above optimization as **S_UniBin**, **S_NeighborBin** and **S_CliqueBin** respectively.

6. EXPERIMENTAL EVALUATION

6.1 Data Set and Experimental Settings

We conducted our experiments on Twitter data. The authors in [22] published a Twitter social graph dataset consisting of more than 660,000 Twitter authors (accounts). Computing the author similarity graph for the whole data set would be prohibitive, as it requires comparing all pairs of authors. Instead, we used a subgraph of 20,150 authors obtained by randomly picking an initial author, and adding authors that are reachable through Breadth First Search on the follower-followee graph.

We computed all pairwise author similarity for these 20,150 Twitter authors. The author similarity distribution is depicted in Figure 9, where the x-axis shows the author similarity value and y-axis shows the fraction of author pairs with similarity values larger than the value indicated by x-axis. It shows that 2.3% author pairs are with similarity ≥ 0.2 and 0.6% pairs are with similarity ≥ 0.3 .

Further, we crawled the tweets of these twitter authors using Twitter REST API² for one day. The tweets data set contains 233,311 tweets, which means these Twitter authors post slightly over 10 tweets per author per day. After we removed some short tweets that have less than two words or only contain meaningless tokens, there are 213,175 tweets left.

We implemented all algorithms in Java. We ran our experiments on machines with Quad Core Intel(R) Xeon(R) E3-1230 v2@3.30GHz CPU and 16GB RAM.

6.2 Performance of the algorithms for SPSP

In this section, we evaluate the performance of the three algorithms for SPSP. We assume that a user follows all the Twitter authors in our dataset, and we run the algorithms on the user's post stream which consists of 213,175 posts in one day.

First, we study the effect of the three diversity dimensions: time, content and author. Figure 10 shows the number of tweets left after diversification under different settings by removing diversity dimensions and varying diversity thresholds. Incorporating all three diversity dimensions with reasonable diversity thresholds, the di-

²<https://dev.twitter.com/overview/documentation>

Figure 9: Author similarity distribution in our data set

versification model prunes about 10% redundant posts. We notice that incorporating only some of these dimensions will largely change the size of diversified stream. It means that all three dimensions play an important role in diversifying tweet data.

6.2.1 Performance of the algorithms under different diversity settings

The analysis in Section 4.4 indicates that the performance of the three algorithms for SPSP is effected by several factors such as the diversity thresholds and the post stream throughput. These diversity settings could change the relative performance between the three algorithms. In this section, we study the performance of each algorithm under different settings and we experimentally show that each algorithm outperforms the other two in certain settings. Supported by former analysis and experimental results, we will summarize use cases for each algorithm.

Varying time diversity threshold λ_t . In Figure 11, we present the performance of UniBin, NeighborBin and CliqueBin under different time diversity thresholds (λ_t). In this experiment, we set $\lambda_c = 18$ (according to the results in Figure 4) and $\lambda_a = 0.7$ (i.e., we consider two authors are similar if the cosine similarity between

Figure 10: Number of tweets left after applying diversification in our data set

their followee vector is ≥ 0.3 and thus distance is ≤ 0.7). The running time shows the execution time for an algorithm to ingest the 213,175 posts.

In Figure 11a we can see that the running time of all three algorithms decreases with smaller λ_t s. The reason is that with a smaller λ_t , the algorithms perform fewer pairwise post comparisons (depicted in Figure 11c). NeighborBin and CliqueBin outperform UniBin in terms of running time. We also notice that CliqueBin is more efficient than NeighborBin when λ_t is small (e.g., ≤ 10 minutes). This gives us evidence for the summarization of use cases in Table 4 for NeighborBin and CliqueBin.

Smaller λ_t also reduces the RAM consumption because the algorithms store shorter history of Z in post bins. As expected, NeighborBin requires more memory than UniBin and CliqueBin.

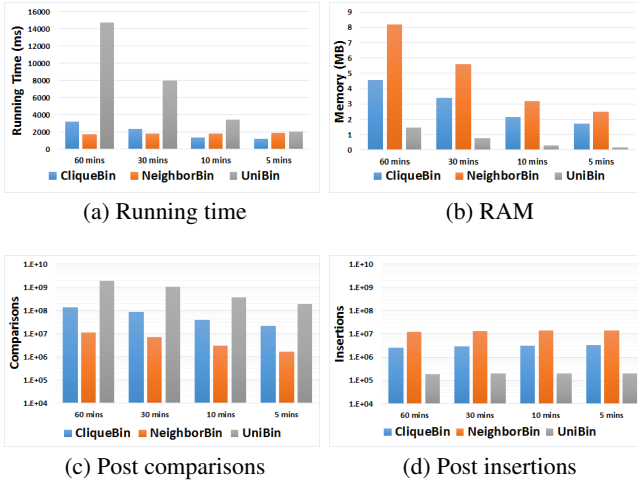

Figure 11: Performance of the three algorithms under different time diversity thresholds λ_t .

Varying content diversity threshold λ_c . We also study the performance of the three algorithms by varying λ_c . For this, we set $\lambda_t = 30$ mins and $\lambda_a = 0.7$ and we vary the λ_c from 9 to 18. Figure 12 depicts the results. It shows that, for all the three algorithms, the change of content diversity threshold only slightly affects the performance. The reason is that SimHash can effectively detect tweets with near-duplicate content for $\lambda_c \geq 9$ as we can see in Figure 4. With λ_c changing from 9 to 18, the precision is already stable. The recall is lower with smaller λ_c , which means more posts will be detected as non-redundant. But this increase in number of

non-redundant posts is slight, and thus the increase in the number of comparisons and insertions does not affect the overall efficiency significantly.

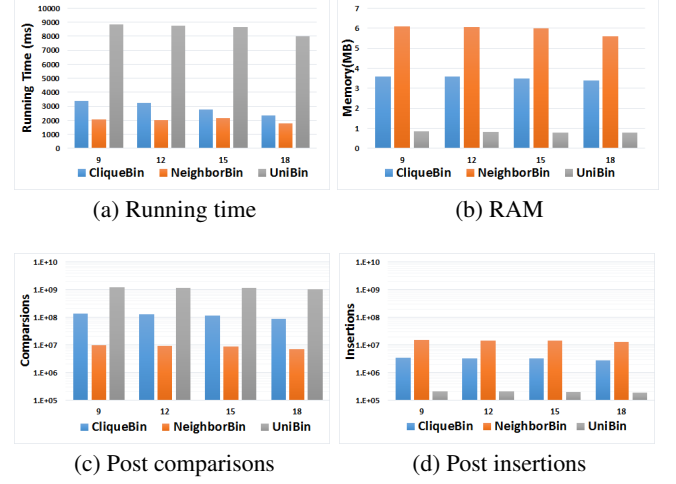

Figure 12: Performance of the three algorithms under different content diversity thresholds λ_c .

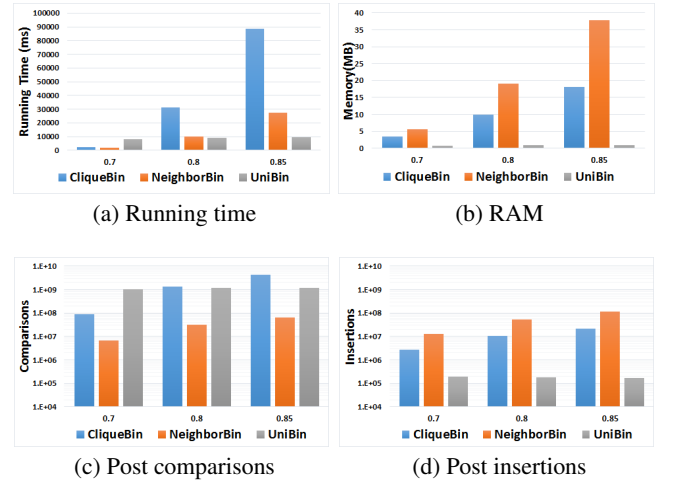

Figure 13: Performance of the three algorithms under different author diversity thresholds λ_a .

Varying author diversity threshold λ_a . Further, we study the performance by varying λ_a . The results are presented in Figure 13 where we set $\lambda_t = 30$ mins and $\lambda_c = 18$.

We observe that the author diversity threshold λ_a significantly affects the overall performance of NeighborBin and CliqueBin but not UniBin. When λ_a increases, the author similarity graph gets denser and thus the number of neighbors per author and the number of cliques per author both increase. For instance, when $\lambda_a = 0.7$ the number of neighbors per author (d) is 113.7, the number of cliques per author (c) is 29 and the average size of a clique (s) is 20 in our data set. They change to 437.3, 106 and 38 correspondingly with $\lambda_a = 0.8$. Hence, the number of copies per post in NeighborBin and CliqueBin increases. This explains that in Figure 13 the memory consumption by NeighborBin and CliqueBin

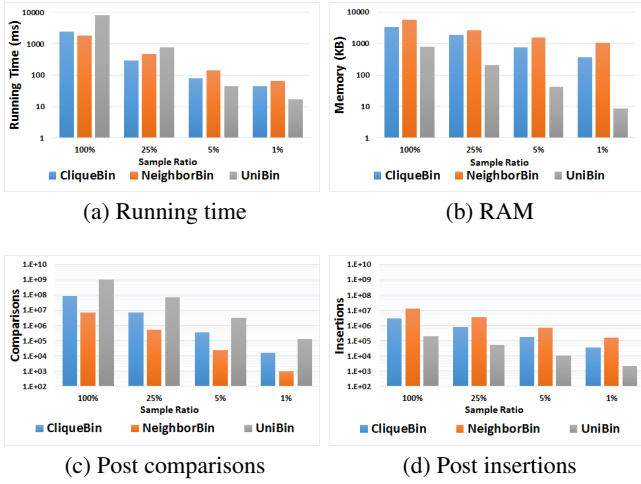

Figure 14: Performance of the three algorithms under different post rates.

increases sharply with larger λ_a s. However, the number of non-duplicate posts does not vary much with different λ_a s in our data set; thus the performance of UniBin is stable.

We note that when λ_a is large the performance of NeighborBin and CliqueBin (in terms of both memory consumption and running time) is significantly worse than UniBin. Hence, we expect UniBin is the best choice among these three algorithms in use cases where λ_a is large, as we summarize in Table 4.

Varying post stream throughputs. We also study the performance of the algorithms under different post stream throughputs. We test this in two ways: (i) varying subscriptions’ post rate, and (ii) varying the number of subscriptions. For both, we keep $\lambda_t = 30 \text{ mins}$, $\lambda_a = 0.7$ and $\lambda_c = 18$.

Varying post generation rate. For this, we randomly sample the posts from the 21,050 authors and solve SPSP on the sampled post stream. We conduct experiments for the sample ratio 25%, 5% and 1% and present the results in Figure 14. The results show that when the throughput is low (the same ratio is low) UniBin outperforms the other two algorithms. We can also see that CliqueBin performs better than NeighborBin with a moderate or small post generation rate.

Varying the number of subscribed authors. The results shown above are for the case of one user subscribing (following) all Twitter authors in our dataset. In this experiment, we randomly sample Twitter authors in our dataset with different sample sizes. We assume that a user subscribes to all authors in one sample and we run the algorithms on the user’s post stream. The results in Figure 15 show that UniBin slightly outperforms the other two when the number of subscriptions is small.

To summarize, UniBin delivers better performance than NeighborBin and CliqueBin when the stream throughput is low. This is consistent with our analysis in Section 4.4 – see also Table 4.

6.2.2 Discussion

Through extensive experiments, we observe that each algorithm outperforms the other two in certain cases. In Table 4 we summarize the best choice of algorithm in different use cases based on our analysis and experimental study.

UniBin is the most memory efficient among the three algorithms. Thus in applications with limited RAM UniBin should be consid-

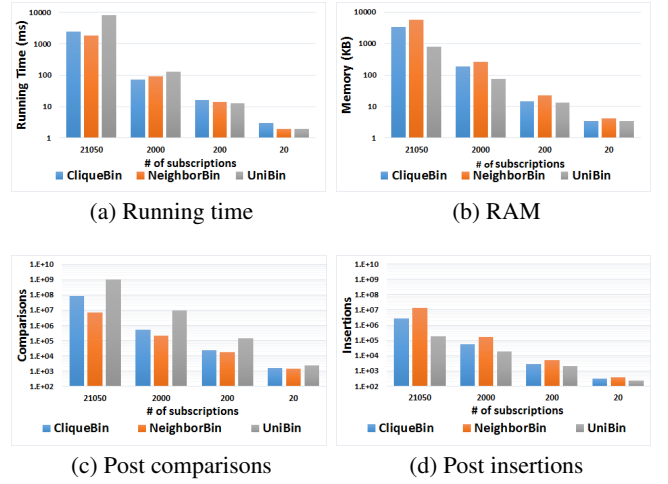

Figure 15: Performance of the three algorithms varying the number of subscribed authors.

ered. Further, when the stream throughput is low (we tested it with small number of subscriptions and low post generation rate), UniBin performs better than the other two. According to the analysis in Table 2, we expect that the number of comparisons increases super-linearly with n (the number of posts in a λ_t time range), however the number of insertions increases sub-linearly with n . With a lower stream throughput (smaller n) the overhead of insertions in NeighborBin and CliqueBin is a large contribution to the total running time. When n is small enough, the overhead on insertions becomes larger than the saving on comparisons for NeighborBin and CliqueBin compared with UniBin. The similar reasoning can be applied to explain why UniBin is the best choice when λ_t is very small. To clarify, in Figure 11 we did not include the results by setting $\lambda_t = 1 \text{ min}$ where UniBin performs best among the three algorithms. We argued that with a larger λ_a both d (number of neighbors per author) and c (number of cliques per author) increase and thus NeighborBin and CliqueBin both have higher number of comparisons and insertions. Thus we can see UniBin is preferable when λ_a is set large. One example use case for UniBin is News RSS Feed reader, where the author similarity graph is dense. Generally, news agents form clusters (e.g., by their political views) such that in each cluster the news agents are similar to each other from a user’s perspective. Another use case could be Google Scholar where the post (scientific publication) throughput is low.

In other cases, CliqueBin or NeighborBin will be the better choice. They both perform well in cases with a high or moderate stream throughput, which is very common for online social networks. The tie breaker between them is the time diversity threshold λ_t , as we analyzed λ_t determines the tradeoffs between costs of comparisons and insertions. CliqueBin is a better choice if λ_t is set moderately. For example, in Twitter information is time sensitive and thus people may be interested in reading posts with related content but with time distance larger than, say, minutes. For applications where the value of λ_t could be in hours or even days, NeighborBin can be applied. For example, Twitch³ is a platform on which people can watch and share video game shows. Users may not be interested in watching the video record of the same match that posted at different time. Even in Twitter some users may prefer to customize the λ_t to a larger value, in order to reduce the post volume if they

Table 4: Use cases of the three algorithms for SPSP

Conditions	Algorithm choice	Example use case
Very small λ_t OR low stream throughput OR large λ_a (dense G) OR RAM is a critical limitation	UniBin	News RSS Feed, Google Scholar
Large λ_t AND small λ_a (sparse G) AND high stream throughput	NeighborBin	Twitch
Moderate λ_t AND small λ_a (sparse G) AND high stream throughput	CliqueBin	Twitter

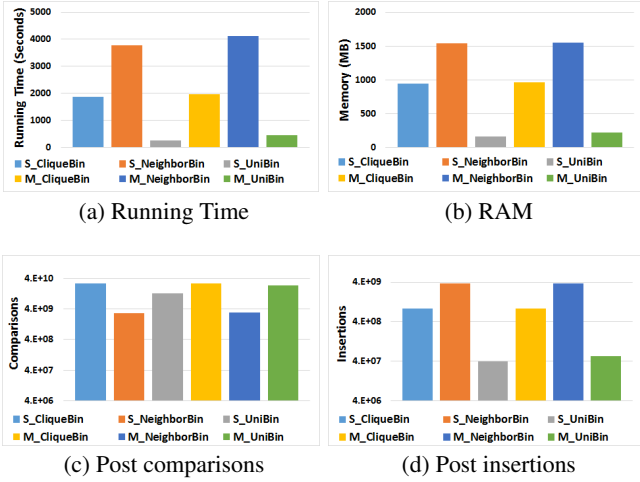

Figure 16: Performance of the algorithms for M-SPSP.

follow a large number of authors.

6.3 Performance of the algorithms for M-SPSP

We consider now the scenario where each Twitter author is also a user. Each user subscribes to (follows) a set of authors which we can get from the original follower-followee social graph. Then we run the algorithms solving M-SPSP for these 21,050 users in our data set. For the experiments in this section, we set $\lambda_t = 30$ mins, $\lambda_a = 0.7$ and $\lambda_c = 18$.

The average number of subscriptions in our sampled user data set is 443.6 and the median is 187. Since we only crawled the posts and computed the author similarity graph for the set of 21,050 authors, we ignored the subscriptions that are not in this set. Then the average number of subscriptions per user drops to 130 and the median is 20. We should note that this reduces the probability of different users sharing common subscriptions.

Figure 16 presents the performance of the algorithms. It shows that the proposed optimization (reusing computation and data structure across multiple users described in Section 5) improves time efficiency as well as memory consumption. Specifically, S_UniBin uses 43% less running time and 27% less memory than M_UniBin. In the S_UniBin method, posts are stored separately by connected components. This reduces the number of comparisons significantly over M_UniBin. We also observe that S_NeighborBin reduces the running time of M_NeighborBin by 8% while S_CliqueBin improves M_NeighborBin by 4% in running time.

S_UniBin achieves superior performance. We also notice that

S_NeighborBin requires fewer post comparisons than S_UniBin but many more insertions. We think that S_UniBin outperforms S_NeighborBin and S_CliqueBin also because its post access pattern is sequential while in the other two are not (each post bin is a map).

7. RELATED WORK

Time Aware Diversity. The authors of [7] solve the problem of maintaining the k most diverse results in a sliding window over a stream. MaxMin semantics is used. They maintain a data structure called the cover tree and show how to incrementally add new and remove expired results from this tree. The cover tree cannot be used for our diversity semantics because it cannot handle simultaneous similarity in three dimensions: time, content and author.

Diversification on Microblogging Posts. The work of [4] studies the problem of diversifying posts in microblogging systems. In their problem setting, users subscribe several queries (topics). However, in practice users are more often subscribing to authors, which is the setting of the problem we studied in this paper. In [4] they apply strict coverage semantics similar to ours, but limited only to time and content diversity. Unlike in our model, in [4] the content diversity is guided by the inputted queries where no inter-post content similarity is considered. They also studied the stream variation of their problem in which they allow a lag upon a new post to decide whether it should be outputted. In our problem, the diversity model is required to make the decision immediately at the arrival of a post.

Document Stream Summarization. The authors of [20] work on the problem of summarizing a Twitter stream. They model the summarization problem as a facility location problem. Give a budget of k , they aim to select k tweets that maximize the similarity to the whole tweets set. They incorporate the time factor to measure the document similarity of two posts. But unlike in our problem, instead of using a hard (boolean) threshold, they consider an exponential decay to the content similarity based on their timestamp difference. In the work of [13], the authors apply clustering techniques for Twitter stream summarization. Tweets are clustered according to content similarity. For each cluster, they build a word graph or phrase graph and pick frequent sentences (“paths” in the graph) to construct a summary. The sentences in the summary may not be in any original tweet. The authors of [18] propose a one-pass online clustering algorithm to cluster tweets, and then they generate online summaries by selecting k tweets (one from each cluster) that have high LexRank [8] score. In [16], the authors apply topic modeling for personalized time-aware tweet summarization. However, all these work do not consider author similarity to measure the similarity between tweets.

Detecting Duplicate Tweets. In [21], the authors propose to use machine learning methods to detect near-duplicates in tweets. For

this, they construct a rich set of syntactic, semantic and contextual features. They aim to distinguish different levels of near-duplicates, e.g. exact copy, strong near-duplicate, or weak near-duplicate.

8. CONCLUSION

In this paper, we studied the novel problem of diversifying social post streams by incorporating diversity in three dimensions: content, time and author. We illustrated the challenges of solving the problem and proposed various algorithms to efficiently handle these challenges. We showed the tradeoffs between our proposed algorithms and argued the use cases for them. We also studied the problem of applying the proposed diversification model for multiple users in a social system. Extensive experiments proved the effectiveness of our model and efficiency of proposed algorithms.

ABSTRACT

Social content such as blogs, tweets, news etc. is a rich source of interconnected information. We identify a set of requirements for the meaningful exploitation of such rich content, and present a new data model, called $S3$, which is the first to satisfy them. $S3$ captures *social* relationships between users, and between users and content, but also the *structure* present in rich social content, as well as its *semantics*. We provide the first top- k keyword search algorithm taking into account the social, structured, and semantic dimensions and formally establish its termination and correctness. Experiments on real social networks demonstrate the efficiency and qualitative advantage of our algorithm through the joint exploitation of the social, structured, and semantic dimensions of $S3$.

1. INTRODUCTION

The World Wide Web (or Web, in short) was designed for users to interact with each other by means of pages interconnected with hyperlinks. Thus, the Web is the earliest inception of an *online* social network (whereas “real-life” social networks have a much longer history in social sciences). However, the technologies and tools enabling large-scale online social exchange have only become available recently. A popular model of such exchanges features: *social network users*, who may be connected to one another, *data items*, and the possibility for users to *tag* data items, i.e., to attach to an item an annotation expressing the user’s view or classification of the item. Variants of this “user-item-tag” (UIT) model can be found e.g., in [18, 21, 30]. In such contexts, a user, called *seeker*, may ask a query, typically as a set of keywords. The problem then is to find the best query answers, taking into account both the relevance of items to the query, and the social proximity between the seeker and the items, based also on tags. Today’s major social networks e.g., Facebook [7], all implement some UIT variant. We identify a set of basic requirements which UIT meets:

R0. UIT models *explicit social connections* between users, e.g., u_1 is a friend of u_0 in Figure 1, to which we refer throughout this paper unless stated otherwise. It also captures *user endorsement (tags)* of data items, as UIT search algorithms *exploit both the user endorsement and the social connections* to return items most likely to interest the seeker, given his social and tagging behavior.

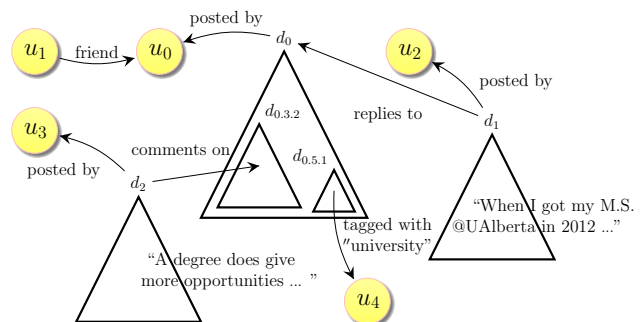

Figure 1: Motivating example.

To fully exploit the content shared in social settings, we argue that the model used for such data (and, accordingly, the query model) must also satisfy the requirements below:

R1. The current wealth of publishing modes (through social networks, blogs, interlinked Web pages etc.) allows many different relations between items. For example, document d_1 *replies to* document d_0 (think for instance of opposite-viewpoint articles in a heated debate), while document d_2 *comments on* the paragraph of d_0 identified by the URI $d_{0.3.2}$. The model must capture **relations between items**, in particular since **they may lead to implicit relations between users**, according to their manipulations of items. For instance, the fact that u_2 posted d_1 as a reply to d_0 , posted by u_0 , entails that u_2 at least read d_0 , and thus some form of exchange has taken place between u_0 and u_2 ; if one looked for *explicit* social connections only, we would wrongly believe that u_0 and u_2 have no relation to each other.

R2. Items shared in social media often have a rich structured content. For instance, the article d_0 comprises many sections, and paragraphs, such as the one identified by the URI $d_{0.3.2}$. **Document structure must be reflected in the model** in order to return *useful* document fragments as query results, instead of a very large document or a very small snippet of a few words (e.g., exactly the search keywords). Document structure also helps discern when users have *really* interacted through content. For instance, u_3 has interacted with u_0 , since u_3 comments on the fragment $d_{0.3.2}$ of u_0 ’s article d_0 . In contrast, when user u_4 tags with “university” the fragment $d_{0.5.1}$ of d_0 , disjoint from $d_{0.3.2}$, u_4 may not even have read the same text as u_3 , thus the two likely did not interact.

R3. **Item and tag semantics** must be modelled. Social Web data encapsulates users’ knowledge on a multitude of topics; ontologies, either general such as DBpedia or Google’s Knowledge Base, or application-specific, can be leveraged to *give query answers which cannot be found without relying on semantics*. For instance, assume u_1 looks for information about *university graduates*: document d_1 states that u_2 holds a M.S. degree. Assume a knowledge base specifies that *a M.S. is a degree* and that *someone*

U URIs	L literals	\mathcal{K} keywords	$Ext(k)$ extension of k
Ω users	D documents	T tags	I graph instance

Table 1: Main data model notations.

having a degree is a graduate. The ability to return as result the snippet of d_1 most relevant to the query is directly conditioned by the ability to exploit the ontology (and the content-based interconnections along the path: u_1 friend of u_0 , u_0 posted d_0 , d_1 replied to d_0).

R4. In many contexts, tagging may apply to tags themselves, e.g., in annotated corpora, where an annotation (tag) obtained from an analysis can further be annotated with provenance details (when and how the annotation was made) or analyzed in its turn. Information from higher-level annotations is obviously still related to the original document. The model should allow expressing **higher-level tags**, to exploit their information for query answering.

R5. The data model and queries should have **well-defined semantics**, to precisely characterize computed results, ensure correctness of the implementation, and allow for optimization.

R6. The model should be **generic** (not tied to a particular social network model), **extensible** (it should allow easy extension or customization, as social networks and applications have diverse and rapidly evolving needs), and **interoperable**, i.e., it should be possible to get richer / more complete answers by integrating different sources of social connections, facts, semantics, or documents. This ensures in particular independence from any proprietary social network viewpoint, usefulness in a variety of settings, and a desirable form of “monotonicity”: the more content is added to the network, the more its information value increases.

This work makes the following contributions.

1. We present $S3$, a novel *data model* for structured, semantic-rich content exchanged in social applications; it is the first model to meet the requirements **R0** to **R6** above.
2. We revisit *top-k social search for keyword queries*, to retrieve the most relevant *document fragments* w.r.t. the social, structural, and semantical aspects captured by $S3$. We identify a set of *desirable properties of the score function* used to rank results, provide a *novel query evaluation algorithm* called $S3_k$ and *formally establish its termination and correctness*; the algorithm intelligently exploits the score properties to stop *as early as possible*, to return answers fast, with little evaluation effort. $S3_k$ is the first to formally guarantee a specific result in a structured, social, and semantic setting.
3. We implemented $S3_k$ based on a concrete score function (extending traditional ones from XML keyword search) and experimented with *three real social datasets*. We demonstrate the *feasibility* of our algorithm, and its *qualitative advantage* over existing approaches: it finds relevant results that would be missed by ignoring any dimension of the graph.

An $S3$ instance can be exploited in many other ways: through structured XML and/or RDF queries as in [9], searching for users, or focusing on annotations as in [4]; one could also apply graph mining etc. In this paper, we first describe the data model, and then revisit the top-k document search problem, since it is the most widely used (and studied) in social settings.

In the sequel, Section 2 presents the $S3$ data model, while Section 3 introduces a notion of generic score and instantiates it through a concrete score. Section 4 describes $S3_k$, we present experiments in Section 5, then discuss related works in Section 6 and conclude.

2. DATA MODEL

We now describe our model integrating social, structured, and semantic-rich content into a *single weighted RDF graph*, and based on a small set of *$S3$ -specific RDF classes and properties*. We

Constructor	Triple	Relational notation
Class assertion	$s \text{ type } o$	$o(s)$
Property assertion	$s \text{ p } o$	$p(s, o)$
Constructor	Triple	Relational notation
Subclass constraint	$s \prec_{sc} o$	$s \subseteq o$
Subproperty constraint	$s \prec_{sp} o$	$s \subseteq o$
Domain typing constraint	$s \leftrightarrow_d o$	$\Pi_{\text{domain}}(s) \subseteq o$
Range typing constraint	$s \hookrightarrow_r o$	$\Pi_{\text{range}}(s) \subseteq o$

Figure 2: RDF (top) and RDFS (bottom) statements.

present weighted RDF graphs in Section 2.1, and show how they model social networks in Section 2.2. We add to our model structured documents in Section 2.3, and tags and user-document interactions in Section 2.4; Section 2.5 introduces our notion of social paths. Table 1 recaps the main notations of our data model.

URIs and literals We assume given a set U of Uniform Resource Identifiers (URIs, in short), as defined by the standard [28], and a set of literals (constants) denoted L , disjoint from U .

Keywords We denote by \mathcal{K} the set of all possible *keywords*: it contains all the URIs, plus the stemmed version of all literals. For instance, stemming replaces “graduation” with “graduate”.

2.1 RDF

An *RDF graph* (or *graph*, in short) is a set of *triples* of the form $s \text{ p } o$, stating that the *subject* s has the *property* p and the value of that property is the *object* o . In relational notation (Figure 2), $s \text{ p } o$ corresponds to the tuple (s, o) in the binary relation p , e.g., u_1 hasFriend u_0 corresponds to $\text{hasFriend}(u_1, u_0)$. We consider every triple is *well-formed* [27]: its subject belongs to U , its property belongs to U , and its object belongs to \mathcal{K} .

Notations We use s , p , o to denote a subject, property, and respectively, object in a triple. Strings between quotes as in “*string*” denote literals.

RDF types and schema The property type built in the RDF standard is used to specify to which *classes* a resource belongs. This can be seen as a form of resource typing.

A valuable feature of RDF is RDF Schema (RDFS), which allows enhancing the resource descriptions provided by RDF graphs. An RDF Schema declares *semantic constraints* between the classes and the properties used in these graphs, through the use of four RDF built-in properties. These constraints can model:

- subclass relationships, which we denote by \prec_{sc} ; for instance, any *M.S.Degree* is also a *Degree*;
- subproperty relationships, denoted \prec_{sp} ; for instance, *workingWith* someone also means being *acquaintedWith* him;
- typing of the first attribute (or domain) of a property, denoted \leftrightarrow_d , e.g., the domain of *hasDegreeFrom* is a *Graduate*;
- typing of the second attribute (or range) of a property, denoted \hookrightarrow_r , e.g., the range of *hasDegreeFrom* is an *University*.

Figure 2 shows the constraints we use, and how to express them. In this figure, domain and range denote respectively the first and second attributes of a property. The figure also shows the relational notation for these constraints, which in RDF are interpreted under the open-world assumption [1], i.e., as *deductive constraints*. For instance, if a graph includes the triples $\text{hasFriend} \leftrightarrow_d \text{Person}$ and $u_1 \text{ hasFriend } u_0$, then the triple $u_1 \text{ type Person}$ holds in this graph even if it is not explicitly present. This *implicit* triple is due to the \leftrightarrow_d constraint in Figure 2.

Saturation RDF entailment is the RDF reasoning mechanism that allows making explicit all the implicit triples that hold in an RDF graph G . It amounts to repeatedly applying a set of normative immediate *entailment* rules (denoted \vdash_{RDF}^i) on G : given some triples

explicitly present in G , a rule adds some triples that directly follow from them. For instance, continuing the previous example,

$$u_1 \text{ hasFriend } u_0, \text{ hasFriend } \hookrightarrow_r \text{ Person } \vdash_{\text{RDF}}^i u_0 \text{ type Person}$$

Applying immediate entailment \vdash_{RDF}^i repeatedly until no new triple can be derived is known to lead to a unique, finite fixpoint graph, known as the *saturation* (a.k.a. closure) of G . RDF entailment is part of the RDF standard itself: the answers to a query on G must take into account all triples in its saturation, since *the semantics of an RDF graph is its saturation* [27].

In the following, we assume, without loss of generality, that all RDF graphs are saturated; many saturation algorithms are known, including incremental [10] or massively parallel ones [26].

Weighted RDF graph Relationships between documents, document fragments, comments, users, keywords etc. naturally form a graph. We encode each edge from this graph by a *weighted RDF triple* of the form (s, p, o, w) , where (s, p, o) is a regular RDF triple, and $w \in [0, 1]$ is termed the *weight* of the triple. Any triple whose weight is not specified is assumed to be of weight 1.

We define the saturation of a weighted RDF graph as the saturation derived *only from its triples whose weight is 1*. Any entailment rule of the form $a, b \vdash_{\text{RDF}}^i c$ applies only if the weight of a and b is 1; in this case, the entailed triple c also has the weight 1. We restrict inference in this fashion to distinguish triples which certainly hold (such as: “a M.S. is a degree”, “ u_1 is a friend of u_0 ”) from others whose weight is computed, and carries a more quantitative meaning, such as “the similarity between d_0 and d_1 is 0.5 ”¹.

Graph instance I and S3 namespace We use I to designate the weighted RDF instance we work with. The RDF Schema statements in I allow a semantic interpretation of keywords, as follows:

DEFINITION 2.1 (KEYWORD EXTENSION). *Given an S3 instance I and a keyword $k \in \mathcal{K}$, the extension of k , denoted $\text{Ext}(k)$, is defined as follows:*

- $k \in \text{Ext}(k)$
- for any triple of the form $b \text{ type } k, b \prec_{\text{sc}} k$ or $b \prec_{\text{sp}} k$ in I , we have $b \in \text{Ext}(k)$.

For example, given the keyword *degree*, and assuming that $\text{M.S.} \prec_{\text{sc}} \text{degree}$ holds in I , we have $\text{M.S.} \in \text{Ext}(\text{degree})$. The extension of k does not generalize it, in particular it does not introduce any loss of precision: whenever k' is in the extension of k , the RDF schema in I ensures that k' is an *instance*, or a *specialization* (particular case) of k . This is in coherence with the principles behind the RDF schema language².

For our modeling purposes, we define below a small set of RDF classes and properties used in I ; these are shown prefixed with the S3 namespace. The next sections show how I is populated with triples derived from the users, documents and their interactions.

2.2 Social network

We consider a set of social network users $\Omega \subset U$, i.e., each user is identified by a URI. We introduce the special RDF class S3:user, and for each user $u \in \Omega$, we add: $u \text{ type S3:user} \in I$.

¹One could generalize this to support inference over triples of any weight, leading to e.g., “ u_1 is of type Person with a weight of 0.5”, in the style of probabilistic databases.

²One could also allow a keyword $k' \in \text{Ext}(k)$ which is only close to (but not a specialization of) k , e.g., “student” in $\text{Ext}(\text{“graduate”})$, at the cost of a loss of precision in query results. We do not pursue this alternative here, as we chose to follow standard RDF semantics.

To model the relationships between users, such as “friend”, “co-worker” etc., we introduce the special property S3:social, and model any concrete relationship between two users by a triple whose property specializes S3:social. Alternatively, one may see S3:social as the *generalization of all social network relationships*.

Weights are used to encode the strength w of each relationship going from a user u_1 to a user u_2 : $u_1 \text{ S3:social } u_2 \ w \in I$. As customary in social network data models, the higher the weight, the closer we consider the two users to be.

Extensibility Depending on the application, it may be desirable to consider that two users satisfying some condition are involved in a social interaction. For instance, if two people have worked the same year for a company of less than 10 employees (such information may be in the RDF part of our instance), they must have *worked together*, which could be a social relationship. This is easily achieved with a query that retrieves all such user pairs (in SPARQL or in a more elaborate language [9] if the condition also carries over the documents), and builds a $u \text{ workedWith } u'$ triple for each such pair of users. Then it suffices to add these triples to the instance, together with the triple: $\text{workedWith} \prec_{\text{sp}} \text{S3:social}$.

2.3 Documents and fragments

We consider that content is created under the form of structured, tree-shaped *documents*, e.g., XML, JSON, etc. A document is an unranked, ordered tree of *nodes*. Let N be a set of node names (for instance, the set of allowed XML element and attribute names, or the set of node names allowed in JSON). Any node has a *URI*. We denote by $D \subset U$ the set of all node URIs. Further, each node has a *name* from N , and a *content*, which we view as a *set of keywords* from \mathcal{K} : we consider each text appearing in a document has been broken into words, stop words have been removed, and the remaining words have been stemmed to obtain our version of the node’s text content. For example, in Figure 1, the text of d_1 might become {“M.S.”, “UAlberta”, “2012”}.

We term any subtree rooted at a node in document d a *fragment* of d , implicitly defined by the URI of its root node. The set of fragments (nodes) of a document d is denoted $\text{Frag}(d)$. We may use f to refer interchangeably to a fragment or its URI. If f is a fragment of d , we say d is an *ancestor* of f .

To simplify, we use *document and fragment interchangeably*; both are identified by the URI of their unique root node.

Document-derived triples We capture the *structural relationships* between documents, fragments and keywords through a set of RDF statements using S3-specific properties. We introduce the RDF class S3:doc corresponding to the documents, and we translate:

- each $d \in D$ into the I triple $d \text{ type S3:doc}$;
- each document $d \in D$ and fragment rooted in a node n of d into $n \text{ S3:partOf } d$;
- each node n and keyword k appearing in the content of n into $n \text{ S3:contains } k$;
- each node n whose name is m , into $n \text{ S3:nodeName } m$.

EXAMPLE 2.1. *Based on the sample document shown in Figure 1, the following triples are part of I :*

$$\begin{array}{ll} d_{0.3.2} \text{ S3:partOf } d_{0.3} & d_1 \text{ S3:contains “M.S.”} \\ d_{0.3} \text{ S3:partOf } d_0 & d_1 \text{ S3:nodeName text} \end{array}$$

The following constraints, part of I , model the natural relationships between the S3:doc class and the properties introduced above:

$$\begin{array}{ll} \text{S3:partOf} \hookrightarrow_d \text{S3:doc} & \text{S3:partOf} \hookrightarrow_r \text{S3:doc} \\ \text{S3:contains} \hookrightarrow_d \text{S3:doc} & \text{S3:nodeName} \hookrightarrow_d \text{S3:doc} \end{array}$$

which read: the relationship S3:partOf connects pairs of fragments (or documents); S3:contains describes the content of a fragment; and S3:nodeName associates names to fragments.

Fragment position We will need to assess how closely related a given fragment is to one of its ancestor fragments. For that, we use a function $pos(d, f)$ which returns the *position* of fragment f within document d . Concretely, pos can be implemented for instance by assigning Dewey-style IDs to document nodes, as in [19, 22]. Then, $pos(d, f)$ returns the list of integers (i_1, \dots, i_n) such that the path starting from d 's root, then moving to its i_1 -th child, then to this node's i_2 -th child etc. ends in the root of the fragment f . For instance, in Figure 1, $pos(d_{0.3.2}, d_0)$ may be $(3, 2)$.

2.4 Relations between structure, semantics, users

We now show how dedicated S3 classes and properties are used to encode all kinds of connections between users, content, and semantics in a single S3 instance.

Tags A typical user action in a social setting is to *tag* a data item, reflecting the user's opinion that the item is related to some concept or keyword used in the tag. We introduce the special class S3:relatedTo to account for the multiple ways in which a user may consider that a fragment is related to a keyword. We denote by T the set of all tags.

For example, in Figure 1, u_4 tags $d_{0.5.1}$ with the keyword "university", leading to the triples:

a type S3:relatedTo a S3:hasSubject $d_{0.5.1}$
a S3:hasKeyword "university" a S3:hasAuthor u_4

In this example, a is a *tag* (or *annotation*) resource, encapsulating the various tag properties: its content, who made it, and on what. The tag subject (the value of its S3:hasSubject property) is either a document or another tag. The latter allows to express *higher-level annotations*, when an annotation (tag) can itself be tagged.

A tag may lack a keyword, i.e., it may have no S3:hasKeyword property. Such no-keyword tags model *endorsement* (support), such as like on Facebook, retweet on Twitter, or +1 on Google+.

Tagging may differ significantly from one social setting to another. For instance, star-based rating of restaurants is a form of tagging, topic-based annotation of text by expert human users is another, and similarly a natural language processing (NLP) tool may tag a text snippet as being about some entity. Just like the S3:social property can be specialized to model arbitrary social connections between users, subclasses of S3:relatedTo can be used to model different kinds of tags. For instance, assuming a_2 is a tag produced by a NLP software, this leads to the I triples:

a_2 type NLP:recognize
NLP:recognize \prec_{sc} S3:relatedTo

User actions on documents Users *post* (or *author*, or *publish*) content, modeled by the dedicated property S3:postedBy. Some of this content may be *comments* on (or *replies* / *answers* to) other fragments; this is encoded via the property S3:commentsOn.

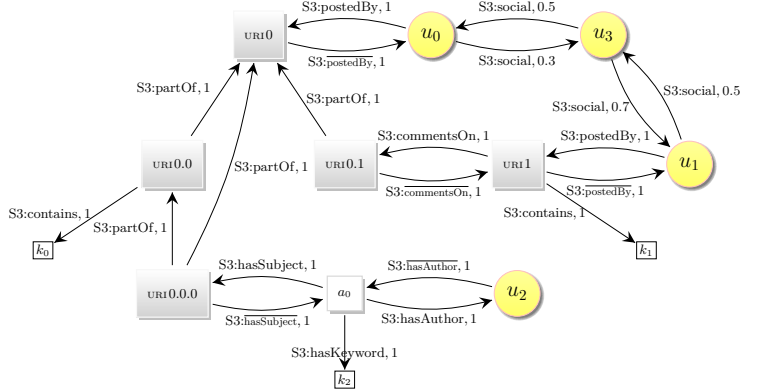

EXAMPLE 2.2. In Figure 1, d_2 is posted by u_3 , as a comment on $d_{0.3.2}$, leading to the following I triples:

d_2 S3:postedBy u_3 d_2 S3:commentsOn $d_{0.3.2}$

As before, we view any concrete relation between documents e.g., *answers to*, *retweets*, *comments on*, *is an old version of* etc. as a specialization (sub-property) of S3:commentsOn; the corresponding connections lead to implicit S3:commentsOn triples, as explained in Section 2.1. Similarly, forms of authorship connecting users to their content are modeled by specializing S3:postedBy.

Class	Semantics
S3:user	the users (the set of its instances is Ω)
S3:doc	the documents (the set of its instances is D)
S3:relatedTo	generalization of item "tagging" with keywords (the set of all instances of this class is T : the set of tags)
Property	Semantics
S3:postedBy	connects users to the documents they posted
S3:commentsOn	connects a comment with the document it is about
S3:partOf	connects a fragment to its parent nodes
S3:contains	connects a document with the keyword(s) it contains
S3:nodeName	asserts the name of the root node of document
S3:hasSubject	specifies the subject (document or tag) of a tag
S3:hasKeyword	specifies the keyword of a tag
S3:hasAuthor	specifies the poster of a tag
S3:social	generalization of social relationships in the network

Table 2: Classes and properties in the S3 namespace.

DEFINITION 2.2 (DOCUMENT VERTICAL NEIGHBORHOOD). Two documents are vertical neighbors if one of them is a fragment of the other. The function $\text{neigh}: U \rightarrow 2^U$ returns the set of vertical neighbors of an URI.

In Figure 3, `URI0` and `URI0.0.0` are vertical neighbors, so are `URI0` and `URI0.1`, but `URI0.0.0` and `URI0.1` are not. In the sequel, due to the strong connections between nodes in the same vertical neighborhood, we consider (when describing and exploiting social paths) that a path entering through any of them can exit through any other; a vertical neighborhood acts like a single node only and exactly from the perspective of a social path⁴. We can now define social paths:

DEFINITION 2.3 (SOCIAL PATH). A social path (or simply a path) in I is a chain of network edges such that the end of each edge and the beginning of the next one are either the same node, or vertical neighbors.

We may also designate a path simply by the list of nodes it traverses, when the edges taken along the path are clear. In Figure 3, $u_2 \xrightarrow{u_2 \text{ S3:hasAuthor } a_0 \ 1} a_0 \xrightarrow{a_0 \text{ S3:hasSubject } \text{URI0.0.0} \ 1} \text{URI0.0.0} \dashrightarrow \text{URI0} \xrightarrow{\text{URI0} \text{ S3:postedBy } u_0 \ 1} u_0$ is an example of such a path (the dashed line: `URI0.0.0` \dashrightarrow `URI0`, is not an edge in the path but a connection between vertical neighbors, `URI0.0.0` been the end of an edge and `URI0` the beginning of the next edge). Also, in this Figure, there is no social path going from `u2` to `u1` avoiding `u0`, because it is not possible to move from `URI0.1` to `URI0.0.0` through a vertical neighborhood.

Social path notations The set of all social paths from a node x (or one of its vertical neighbours) to a node y (or one of its vertical neighbors) is denoted $x \rightsquigarrow y$. The length of a path p is denoted $|p|$. The restriction of $x \rightsquigarrow y$ to paths of length exactly n is denoted $x \rightsquigarrow_n y$, while $x \rightsquigarrow_{\leq n} y$ holds the paths of at most n edges.

Path normalization To harmonize the weight of each edge in a path depending on its importance, we introduce path normalization, which modifies the weights of a path's edge as follows. Let n be the ending point of a social edge in a path, and e be the next edge in this path. The normalized weight of e for this path, denoted $e.n.w$, is defined as:

$$e.n.w = e.w / \sum_{e' \in \text{out}(\text{neigh}(n))} e'.w$$

where $e.w$ is the weight of e , and $\text{out}(\text{neigh}(n))$ the set of network edges outgoing from any vertical neighbor of n . This normalizes the weight of e w.r.t. the weight of edges outgoing from any vertical neighbor of n . Observe that $e.n.w$ depends on n , however e does not necessarily start in n , but in any of its vertical neighbors. Therefore, $e.n.w$ indeed depends on the path (which determines the vertical neighbor n of e 's entry point).

In the following, we assume all social paths are normalized.

EXAMPLE 2.3. In Figure 3, consider the path:

$$p = u_0 \xrightarrow{u_0 \text{ S3:postedBy } \text{URI0} \ 1} \text{URI0} \dashrightarrow \text{URI0.0.0} \xrightarrow{\text{URI0.0.0} \text{ S3:hasSubject } a_0 \ 1} a_0$$

Its first edge is normalized by the edges leaving u_0 : one leading to `URI0` (weight 1) and the other leading to u_3 (weight 0.3). Thus, its normalised weight is $1/(1 + 0/3) = 0.77$.

Its second edge exits `URI0.0.0` after a vertical neighborhood traversal `URI0` \dashrightarrow `URI0.0.0`. It is normalized by the edges leaving $\text{neigh}(\text{URI0})$, i.e., all the edges leaving a fragment of `URI0`. Its normalised weight is $1/(1 + 1 + 1 + 1) = 0.25$.

quire simple changes to the path normalization introduced below.

⁴In other contexts, e.g., to determine their relevance w.r.t. a query, vertical neighbors are considered separately.

S3 meets the requirements from Section 1, as follows. Gener-icity, extensibility and interoperability (**R6**) are guaranteed by the reliance on the Web standards RDF (Section 2.1) and XML/JSON (Section 2.3). These enable specializing the **S3** classes and properties, e.g., through application-dependent queries (see Extensibility in Section 2.2). Our document model (Section 2.3) meets requirement **R2**; the usage of RDF (Section 2.1) ensures **R3**, while the relationships introduced in Section 2.4 satisfy **R1** as well as **R4** (higher-level tags). For what concerns **R5** (formal semantics), the data model has been described above; we consider queries next.

3. QUERYING AN S3 INSTANCE

Users can search **S3** instances through keyword queries; the answer consists of the k top-score fragments, according to a joint structural, social, and semantic score. Section 3.1, defines queries and their answers. After some preliminaries, we introduce a *generic score*, which can be instantiated in many ways, and a set of *feasibility conditions* on the score, which suffice to ensure the termination and correctness of our query answering algorithm (Section 3.3). We present our concrete score function in Section 3.4.

3.1 Queries

S3 instances are queried as follows:

DEFINITION 3.1 (QUERY). A query is a pair (u, ϕ) where u is a user and ϕ is a set of keywords.

We call u the *seeker*. We define the top- k answers to a query as the k documents or fragments thereof with the highest scores, further satisfying the following constraint: the presence of a document or fragment at a given rank precludes the inclusion of its vertical neighbors at lower ranks in the results⁵. As customary, top- k answers are ranked using a score function $s(q, d)$ that returns for a document d and query q a value in \mathbb{R} , based on the graph I .

DEFINITION 3.2 (QUERY ANSWER). A top- k answer to the query q using the score s , denoted $T_{k,s}(q)$, is recursively defined as a top- $k-1$ answer, plus a document with the best score among those which are neither fragments nor ancestors of the documents in the top- $k-1$ answer.

Observe that a query answer may not be unique. This happens as soon as several documents have equal scores for the query, and this score happens to be among the k highest.

3.2 Connecting query keywords and documents

Answering queries over I requires finding best-scoring documents, based on the *direct and indirect connections* between documents, the seeker, and search keywords. The connection can be direct, for instance, when the document contains the keyword, or indirect, when a document is connected by a chain of relationships to a search keyword k , or to some keyword from k 's extension.

We denote the **set of direct and indirect connections between a document d and a keyword k** by $\text{con}(d, k)$. It is a set of three-tuples $(\text{type}, \text{frag}, \text{src})$ such that:

- $\text{type} \in \{\text{S3:contains}, \text{S3:relatedTo}, \text{S3:commentsOn}\}$ is the **type** of the connection,
- $f \in \text{Frag}(d)$ is the **fragment** of d (possibly d itself) due to which d is involved in this connection,
- $\text{src} \in \Omega \cup D$ (users or documents) is the **source** (origin) of this connection (see below).

⁵This assumption is standard in XML keyword search, e.g., [6].

Below we describe the possible situations which create connections. Let d, d' be documents or tags, and f, f' be fragments of d and d' , respectively⁶. Further, let k, k' be keywords such that $k' \in \text{Ext}(k)$, and $\text{src} \in \Omega \cup D$ be a user or a document.

Documents connected to the keywords of their fragments If the fragment f contains a keyword k , then:

$$(\text{S3:contains}, f, d) \in \text{con}(d, k)$$

which reads: “ d is connected to k through a S3:contains relationship due to f ”. This connection holds even if f contains not k itself, but some $k' \in \text{Ext}(k)$. For example, in Figure 1, if the keyword “university” appears in the fragment whose URI is $d_{2.7.5}$, then $\text{con}(d_2, \text{“university”})$ includes $(\text{S3:contains}, d_{2.7.5}, d_2)$. Observe that a given k' and f may lead to many connections, if k' specializes several keywords and/or if f has many ancestors.

Connections due to tags For every tag a of the form

$$\begin{array}{ll} \text{a type S3:relatedTo} & \text{a S3:hasSubject } f \\ \text{a S3:hasAuthor } \text{src} & \text{a S3:hasKeyword } k' \end{array}$$

$\text{con}(d, k)$ includes $(\text{S3:relatedTo}, f, \text{src})$. In other words, whenever a fragment f of d is tagged by a source src with a specialization of the keyword k , this leads to a S3:relatedTo connection between d and k due to f , whose source is the tag author src . For instance, the tag a of u_4 in Figure 1 creates the connection $(\text{S3:relatedTo}, d_{0.5.1}, u_4)$ between d_0 and “university”.

More generally, if a tag a on fragment f has any type of connection (not just S3:hasKeyword) to a keyword k due to source src , this leads to a connection $(\text{S3:relatedTo}, f, \text{src})$ between d and k . The intuition is that the tag adds its connections to the tagged fragment and, transitively, to its ancestors. (As the next section shows, the importance given to such connections decreases as the distance between d and f increases.)

If the tag a on f is a simple endorsement (it has no keyword), the tag inherits d ’s connections, as follows. Assume d has a connection of type type to a keyword k : then, a also has a type connection to k , whose source is src , the tag author. The intuition is that when src endorses (likes, +1s) a fragment, src agrees with its content, and thus connects the tag, to the keywords related to that fragment and its ancestors. For example, if a user u_5 endorsed d_0 in Figure 1 through a no-keyword tag a_5 , the latter tag is related to “university” through: $(\text{S3:relatedTo}, d_{0.5.1}, u_5)$.

Connections due to comments When a comment on f is connected to a keyword, this also connects any ancestor d of f to that keyword; the connection source carries over, while the type of d ’s connection is S3:commentsOn. For instance, in Figure 1, since d_2 is connected to “university” through $(\text{S3:contains}, d_{2.7.5}, d_2)$ and since d_2 is a comment on $d_{0.3.2}$, it follows that d_0 is also related to “university” through $(\text{S3:commentsOn}, d_{0.3.2}, d_2)$.

3.3 Generic score model

We introduce a set of proximity notions, based on which we state the conditions to be met by a score function, for our query evaluation algorithm to compute a top-k query answer.

Path proximity We consider a measure of proximity *along one path*, denoted $\overrightarrow{\text{prox}}$, between 0 and 1 for any path, such that:

- $\overrightarrow{\text{prox}}(()) = 1$, i.e., the proximity is maximal on an empty path (in other words, from a node to itself),
- for any two paths p_1 and p_2 , such that the start point of p_2 is in the vertical neighborhood of the end point of p_1 :

$$\overrightarrow{\text{prox}}(p_1 || p_2) \leq \min(\overrightarrow{\text{prox}}(p_1), \overrightarrow{\text{prox}}(p_2)),$$

⁶We here slightly extend notations, since tags do not have fragments: if d is a tag, we consider that its only fragment is d .

where $||$ denotes path concatenation. This follows the intuition that proximity along a concatenation of two paths is at most the one along each of these two components paths: proximity can only decrease as the path gets longer.

Social proximity associates to two vertices connected by at least one social path, a comprehensive measure over *all the paths* between them. We introduce such a global proximity notion, because different paths traverse different nodes, users, documents and relationships, all of which may impact the relation between the two vertices. Considering all the paths gives a *qualitative* advantage to our algorithm, since it enlarges its knowledge to the types and strength of all connections between two nodes.

DEFINITION 3.3 (SOCIAL PROXIMITY). *The social proximity measure $\text{prox} : (\Omega \cup D \cup T)^2 \rightarrow [0, 1]$, is an aggregation along all possible paths between two users, documents or tags, as follows:*

$$\text{prox}(a, b) = \oplus_{\text{path}}(\{(\overrightarrow{\text{prox}}(p), |p|), p \in a \rightsquigarrow b\}),$$

where $| \cdot |$ is the number of vertices in a path and \oplus_{path} is a function aggregating a set of values from $[0, 1] \times \mathbb{N}$ into a single scalar value.

Observe that the set of all paths between two nodes may be infinite, if the graph has cycles; this is often the case in social graphs. For instance, in Figure 3, a cycle can be closed between $(u_0, \text{URI0}, u_0)$. Thus, in theory, the score is computed over a potentially infinite set of paths. However, in practice, our algorithm works with *bounded social proximity* values, relying only on paths of a bounded length:

$$\text{prox}^{\leq n}(a, b) = \oplus_{\text{path}}(\{(\overrightarrow{\text{prox}}(p), |p|), p \in a \rightsquigarrow_{\leq n} b\})$$

Based on the proximity measure, and the connections between keywords and documents introduced in Section 3.2, we define:

DEFINITION 3.4 (GENERIC SCORE). *Given a document d and a query $q = (u, \phi)$, the score of d for q is:*

$$\text{score}(d, (u, \phi)) = \oplus_{\text{gen}}(\{(k, \text{type}, \text{pos}(d, f), \text{prox}(u, \text{src})) \mid k \in \phi, (\text{type}, f, \text{src}) \in \text{con}(d, k)\})$$

where \oplus_{gen} is a function aggregating a set of (keyword, relationship type, importance of fragment f in d , social proximity) tuples into a value from $[0, 1]$.

Importantly, the above score *reflects the semantics, structure, and social content of the S3 instance*, as follows.

First, \oplus_{gen} aggregates over the keywords in ϕ . Recall that tuples from $\text{con}(d, k)$ account not only for k but also for keywords $k' \in \text{Ext}(k)$. This is how semantics is injected into the score.

Second, the score of d takes into account the relationships between fragments f of d , and keywords k , or $k' \in \text{Ext}(k)$, by using the sequence $\text{pos}(d, f)$ (Section 2.3) as an indication of the structural importance of the fragment within the document. If the sequence is short, the fragment is likely a large part of the document. Document *structure* is therefore taken into account here both *directly* through pos , and *indirectly*, since the con tuples also propagate relationships from fragments to their ancestors (Section 3.2).

Third, the score takes into account the *social* component of the graph through prox : this accounts for the relationships between the seeker u , and the various parties (users, documents and tags), denoted src , due to which f may be relevant for k .

Feasibility properties For our query answering algorithm to converge, the generic score model must have some properties which we describe below.

1. Relationship with path proximity This refers to the relationship between path proximity and score. First, the score should only

increase if one adds more paths between a seeker and a data item. Second, the contribution of the paths of length $n \in \mathbb{N}$ to the social proximity can be expressed using the contributions of shorter “prefixes” of these paths, as follows. We denote by $ppSet^n(a, b)$ the set of the path proximity values for all paths from a to b of length n :

$$ppSet^n(a, b) = \{\overrightarrow{prox}(p) \mid p \in a \leadsto_n b\}$$

Then, the first property is that there exists a function U_{prox} with values in $[0, 1]$, taking as input (i) the bounded social proximity for path of length at most $n - 1$, (ii) the proximity along paths of length n , and (iii) the length n , and such that:

$$prox^{\leq n}(a, b) = prox^{\leq n-1}(a, b) + U_{prox}(prox^{\leq n-1}(a, b), ppSet^n(a, b), n)$$

2. Long paths attenuation The influence of social paths should decrease as they get longer; intuitively, the farther away two items are, the weaker their connection and thus their influence on the score. More precisely, there exists a bound B_{prox}^n tending to 0 as n grows, and such that:

$$B_{prox}^n \geq prox - prox^{\leq n}$$

3. Score soundness The score of a document should be positively correlated with the social proximity from the seeker to the document fragments that are relevant for the query.

Denoting $score_{[g]}$ the score where the proximity function $prox$ is replaced by a continuous function g having the same domain $(\Omega \cup D \cup T)^2$, $g \mapsto score_{[g]}$ must be monotonically increasing and continuous for the uniform norm.

4. Score convergence

This property bounds the score of a document and shows how it relates to the social proximity. It requires the existence of a function B_{score} which takes a query $q = (u, \phi)$ and a number $B \geq 0$, known to be an upper bound on the social proximity between the seeker and any source: for any d , query keyword k , and $(type, f, src) \in con(d, k)$, we know that $prox(u, src) \leq B$. B_{score} must be positive, and satisfy, for any q :

- for any document d , $score(d, q) \leq B_{score}(q, B)$;
- $\lim_{B \rightarrow 0} (B_{score}(q, B)) = 0$ (tends to 0 like B).

We describe a concrete feasible score, i.e., having the above properties, in the next section.

3.4 Concrete score

We start by instantiating \overrightarrow{prox} , $prox$ and $score$.

Social proximity Given a path p , we define $\overrightarrow{prox}(p)$ as the product of the normalized weights (recall Section 2.5) found along the edges of p . We define our concrete social proximity function $prox(a, b)$ as a weighted sum over all paths from a to b :

$$prox(a, b) = C_\gamma \times \sum_{p \in a \leadsto b} \frac{\overrightarrow{prox}(p)}{\gamma^{|p|}}$$

where $\gamma > 1$ is a scalar coefficient, and $C_\gamma = \frac{\gamma-1}{\gamma}$ is introduced to ensure that $prox \leq 1$. Recall that by Definition 3.3, $prox$ requires a \oplus_{path} aggregation over the (social proximity, length) pairs of the paths between the two nodes. Hence, this concrete social proximity corresponds to choosing:

$$\oplus_{path}(S) = C_\gamma \times \sum_{(sp, len) \in S} \frac{sp}{\gamma^{len}}$$

where (sp, len) is a (social proximity, length) pair from its input.

EXAMPLE 3.1. Social proximity Let us consider in Figure 3 the social proximity from u_0 to $URI0$, using the \overrightarrow{prox} and \oplus_{path} previously introduced. An edge connects u_0 directly to $URI0$, leading to the normalized path p :

$$p = u_0 \xrightarrow{u_0 \text{ S3:postedBy } URI0 \frac{1}{1+0.3}} URI0$$

which accounts for a partial social proximity:

$$prox^{\leq 1}(u_0, URI0) = \frac{\overrightarrow{prox}(p)}{\gamma^{|p|}} = \frac{1/(1+0.3)}{\gamma^1}$$

This social proximity generalizes Katz distance [17]; other common distances may be used, e.g., SimRank [14].

Score function We define a simple concrete S3 score function which, for a document d , is the product of the scores of each query keyword in d . The score of a keyword is summed over all the connections between the keyword and the document. The weight for a given connection and keyword only depends on the social distance between the seeker and the sources of the keyword, and the structural distance between the fragment involved in this relation and d , namely the length of $pos(d, f)$. Both distances decrease exponentially as the path length grows. Formally:

DEFINITION 3.5 (S3_k SCORE). Given a query (u, ϕ) , the S3_k score of a document d for the query is defined as:

$$score(d, (u, \phi)) = \prod_{k \in \phi} \left(\sum_{(type, f, src) \in con(d, k)} \eta^{|pos(d, f)|} \times prox(u, src) \right)$$

for some damping factor $\eta < 1$.

Recall from Definition 3.4 that an aggregation function \oplus_{gen} combines the contributions of (keyword, relationship type, importance, social proximity) tuples in the score. The above definition corresponds to the following \oplus_{gen} aggregator:

$$\oplus_{gen}(S) = \prod_{k \in \phi} \left(\sum_{\substack{rel, prox \\ \exists type, (k, type, rel, prox) \in S}} \eta^{|rel|} \times prox \right)$$

Note that if we ignore the social aspects and restrict ourselves to top-k search on documents (which amounts to $prox = 1$), \oplus_{gen} gives the best score to the lowest common ancestor (LCA) of the nodes containing the query keywords. Thus, our score extends typical XML IR works, e.g., [6] (see also Section 6).

Obviously, there are many possible ways to define \oplus_{gen} and \oplus_{path} , depending on the application. In particular, different types of connections may not be accounted for equally; our algorithm only requires a feasible score (with the feasibility properties).

THEOREM 3.1 (SCORE FEASIBILITY). The S3_k score function (Definition 3.5) has the feasibility properties (Section 3.3).

The proof appears in our technical report [3].

4. QUERY ANSWERING ALGORITHM

In this section, we describe our Top-k algorithm called S3_k, which computes the answer to a query over an S3 instance using our S3_k score, and formally state its correctness.

4.1 Algorithm

The main idea, outlined in Algorithm 1, is the following. The instance is explored starting from the seeker and going to other vertices (users, documents, or resources) at increasing distance. At the n -th iteration, the I vertices explored are those connected to the seeker by at least a path of length at most n . We term *exploration border* the set of graph nodes reachable by the seeker through a path of length exactly n . Clearly, the border changes as n grows.

During the exploration, documents are collected in a set of candidate answers. For each candidate c , we maintain a score interval: its currently known lowest possible score, denoted $c.lower$, and its

Algorithm 1: $S3_k$ – Top- k algorithm.

Input : a query $q = (u, \phi)$
Output: the best k answers to q over an $S3$ instance $I, T_{k,s}(q)$

```

1  $candidates \leftarrow []$  // initially empty list
2  $discarded \leftarrow \emptyset$ 
3  $borderPath \leftarrow []$ 

4  $allProx \leftarrow \delta_u$  //  $\delta_u[v] = \begin{cases} 1 & \text{if } v = u \\ 0 & \text{otherwise} \end{cases}$ 

5  $threshold \leftarrow \infty$  // Best possible score of a document not yet explored, updated in ComputeCandidatesBounds
6  $n \leftarrow 0$ 
7 while not StopCondition( $candidates$ ) do
8    $n \leftarrow n + 1$ 
9   ExploreStep()
10  ComputeCandidatesBounds()
11  CleanCandidatesList()
12 return  $candidates[0, k - 1]$ 
```

$q = (u, \phi)$	Query: seeker u and keyword set ϕ
k	Result size
n	Number of iterations of the main loop of the algorithm
$candidates$	Set of documents and/or fragments which are candidate query answers at a given moment
$discarded$	Set of documents and/or fragments which have been ruled out of the query answer
$borderPath[v]$	Paths from u to v explored at the last iteration ($a \rightsquigarrow_n v$)
$allProx[v]$	Bounded social proximity ($prox^{\leq n}$) between the seeker u and a node v , taking into account all the paths from u to v known so far
$connect[c]$	Connections between the seeker and the candidate c : $connect[c] = \{(k, type, pos(d, f), src) k \in \phi, (type, f, src) \in con(c, k)\}$
$threshold$	Upper bound on the score of the documents not visited yet

Table 3: Main variables used in our algorithms.

Algorithm 2: Algorithm StopCondition

Input : $candidates$ set
Output: true if $candidates[0, k - 1]$ is $T_{k,s}(q)$, false otherwise

```

1 if  $\exists d, d' \in candidates[0, \dots, k - 1], d \in neigh(d')$  then
2   return false
3  $min\_topk\_lower \leftarrow \infty$ 
4 foreach  $c \in candidates[0, \dots, k - 1]$  do
5    $min\_topk\_lower \leftarrow \min(min\_topk\_lower, c.lower)$ 
6  $max\_non\_topk\_upper \leftarrow candidates[k].upper$ 
7 return  $\max(max\_non\_topk\_upper, threshold) \leq min\_topk\_lower$  // Boolean result
```

highest possible score, denoted $c.upper$. These scores are updated as new paths between the seeker and the candidates are found. Candidates are kept sorted by their highest possible score; the k first are the answer to the query when the algorithm stops, i.e., when no candidate document outside the current first k can have an upper bound above the minimum lower bound within the top k ranks.

Further, the search algorithm relies on three tables:

- $borderPath$ is a table storing, for a node v in I , the set of paths of length n between u (the seeker) and v , where n is the current distance from u that the algorithm has traversed.
- $allProx$ is a table storing, for a node v in I , the proximity between u and v taking into account all the paths known so far from u to v . Initially, its value is 0 for any $v \neq u$.
- $connect$ is a table storing for a candidate c the set of connections (Section 3.2) discovered so far between the seeker and c

These tables are updated during the search. While they are defined on all the I nodes, we only compute them gradually, for the nodes on the exploration border.

Termination condition Of course, search should not explore the whole graph, but instead stop as early as possible, while returning

Algorithm 3: Algorithm ExploreStep

Update: $borderPath$ and $allProx$

```

1 if  $n = 1$  then
2    $borderPath \leftarrow out(\{u\})$ 
3 else
4   foreach  $v \in I$  do
5      $newBorderPath[v] \leftarrow \emptyset$ 
6   foreach  $p \in borderPath$  do
7     foreach network edge  $e$  in  $out(neigh(p.end))$  do
8        $m \leftarrow e.target$ 
9       if  $m$  is a document or a tag then
10         $GetDocuments(m)$ 
11         $newBorderPath[m].add(p||e)$ 
12    $borderPath \leftarrow newBorderPath$ 
13 foreach  $v \in I$  do
14    $newAllProx[v] \leftarrow allProx[v] + U_{prox}(allProx[v],$ 
15      $\{prox(p), p \in borderPath[v]\}, n)$ 
16  $allProx \leftarrow newAllProx$ 
```

the correct result. To this aim, we maintain during the search an upper bound on the score of all documents unexplored so far, named $threshold$. Observe that we do not need to return the exact score of our results, and indeed we may never narrow down the (lower bound, upper bound) intervals to single numbers; we just need to make sure that no document unexplored so far is in among the top k . Algorithm 2 outlines the procedure to decide whether the search is complete: when (i) the candidate set does not contain documents such that one is a fragment of another, and (ii) no document can have a better score than the current top k .

Any-time termination Alternatively, the algorithm can be stopped at any time (e.g., after exhausting a time budget) by making it return the k best candidates based on their current upper bound score.

Graph exploration Algorithm 3 describes one search step (iteration), which visits nodes at a social distance n from the seeker. For the ones that are documents or tags, the $GetDocuments$ algorithm (see hereafter) looks for related documents that can also be candidate answers (these are added to $candidates$); $discarded$ keeps track of related documents with scores too low for them to be candidates. The $allProx$ table is also updated using the U_{prox} function, whose existence follows from the first score feasibility property (Section 3.3), to reflect the knowledge acquired from the new exploration border ($borderPath$). Observe that Algorithm 3 computes $prox^{\leq n}(u, src)$ iteratively using the first feasibility property; at iteration n , $allProx[src] = prox^{\leq n}(u, src)$.

Computing candidate bounds The $ComputeCandidateBounds$ algorithm (shown in [3]) maintains during the search the lower and upper bounds of the $candidates$, as well as $threshold$. A candidate's lower bound is computed as its score where its social proximity to the user⁷ is approximated by its bounded version, based only on the paths explored so far:

$$\oplus_{gen}(\{(kw, type, pos(d, f), allProx[src]) \mid kw \in \phi, (type, f, src) \in con(d, kw)\})$$

This is a lower bound because, during exploration, a candidate can only get closer to the seeker (as more paths are discovered).

A candidate's upper bound is computed as its score, where the social proximity to the user is replaced by the sum between the bounded proximity and the function $B_{prox}^{>n}(u, src)$, whose existence follows from the long path attenuation property (Section 3.3).

⁷The actual (exact) social proximity requires a complete traversal of the graph; our algorithms work with approximations thereof.

The latter is guaranteed to offset the difference between the bounded and actual social proximity:

$$\oplus_{gen}(\{(kw, type, pos(d, f), allProx[src] + B_{prox}^{>n}(u, src)) \mid kw \in \phi, (type, f, src) \in con(d, kw)\})$$

The above bounds rely on $con(d, k)$, the set of all connections between a candidate d and a query keyword k (Section 3.2); clearly, the set is not completely known when the search starts. Rather, connections accumulate gradually in the *connect* table (Algorithm `GetDocuments`), whose tuples are used as approximate (partial) $con(d, k)$ information in `ComputeCandidateBounds`.

Finally, `ComputeCandidateBounds` updates the relevance threshold using the known bounds on *score* and *prox*. The new bound estimates the best possible score of the unexplored documents.

Cleaning the candidate set Algorithm `CleanCandidateList` removes from *candidates* documents that cannot be in the answer, i.e., those for which k candidates with better scores are sure to exist, as well as those having a candidate neighbor with a better score. The algorithm is delegated to [3].

Getting candidate documents Given a candidate document or tag x , Algorithm `GetDocuments` checks whether some documents unexplored so far, reachable from x through a chain of `S3:partOf`, `S3:commentsOn`, `S3:hasSubject`, or `S3:hasSubject` edges, are candidate answers. If yes, they are added to *candidates* and the information necessary to estimate their score is recorded in *connect*. The algorithm is detailed in [3].

4.2 Correctness of the algorithm

The theorems below state the correctness of our algorithm for any score function with the feasibility properties identified in Section 3.3. The proofs are quite involved, and they are delegated to [3]. The core of the proofs is showing how the score feasibility properties entail a set of useful properties, in particular related to early termination (convergence).

THEOREM 4.1 (STOP CORRECTNESS). *When a stop condition is met, the first k elements in candidates are a query answer.*

We say the tie of two equal-score documents d, d' is *breakable* if examining a set of paths of bounded length suffices to decide their scores are equal. (In terms of our score feasibility properties, this amounts to $B_{prox}^{>n} = 0$ for some n). Our generic score function (Definition 3.5) does not guarantee all ties are breakable. However, any finite-precision number representation eventually brings the lower and upper bounds on d and d' 's scores too close to be distinguished, de facto breaking ties.

THEOREM 4.2 (CORRECTNESS WITH BREAKABLE TIES). *If there exists a query answer of size k and all ties are breakable then Algorithm 1 returns a query answer of size k .*

THEOREM 4.3 (ANYTIME CORRECTNESS). *Using anytime termination, Algorithm 1 eventually returns a query answer.*

In our experiments (Section 5), the threshold-based termination condition was always met, thus we never needed to wait for convergence of the lower and upper bound scores.

5. IMPLEMENTATION & EXPERIMENTS

We describe experiments creating and querying S_3 instances. We present the datasets in Section 5.1, while Section 5.2 outlines our implementation and some optimizations we brought to the search algorithm. We report query processing times in Section 5.3, study the quality of our returned results in Section 5.4, then we conclude.

I ₁ (Twitter)	
Users	492,244
S3:social edges	17 544 347
Documents	467,710
Fragments (non-root)	1,273,800
Tags	609,476
Keywords	28,126,940
Tweets	999,370
Retweets	85%
Reply to users' status	6.9%
String-keyword associations extracted from DBpedia	3,301,425
S3:social edges per user having any (average)	317
Nodes (without keywords)	2 972 560
Edges (without keywords)	24 554 029

I ₂ (Vodkaster)		I ₃ (Yelp)	
Users	5,328	Users	366,715

Fragments (non-root)	529,432	Keywords	59,614,201
Keywords	3,838,662	Businesses	61,184
Movies	20,022		

Figure 4: Statistics on our instances.

5.1 Datasets, queries, and systems

Datasets We built three datasets, I_1 , I_2 , and I_3 , based respectively on content from Twitter, Vodkaster and Yelp.

The instance I_1 was constructed starting from tweets obtained through the public streaming Twitter API. Over a one-day interval (from May 2nd 2014 16h44 GMT to May 3rd 2014 12h44 GMT), we gathered roughly one million tweets. From every tweet that is not a retweet, we created a document having three nodes (i) a *text* node: from the *text* field of the tweet, we extracted named entities and words (using the Twitter NLP tools library [20]) and matched them against a general-purpose ontology we created from DBpedia (see below); (ii) a *date* node, and (iii) a *geo* node: if the tweet included a human readable location, we inserted it in this node. The RDF graph of our instance was built from DBpedia datasets, namely: *Mapping-based Types*, *Mapping-based Properties*, *Persondata* and *Lexicalizations Dataset*. These were chosen as they were the most likely to contain concepts (names, entities etc.) occurring in tweets. Tweet text was *semantically enriched* (connected to the RDF graph) as follows: within the *text* fields, we replaced each word w for which a triple of the form $u \text{ foaf:name } w$ holds in the DBpedia knowledge base, by the respective URI u .

When a tweet t' authored by user u is a *retweet* of another tweet t , for each hashtag h introduced by t' , we added to I_1 the triples: a type `S3:relatedTo`, a `S3:hasSubject` t , a `S3:hasKeyword` h and a `S3:hasAuthor` u . If a tweet t'' was a *reply* to another tweet t , we considered t'' a comment on t . Whenever t was present in our dataset⁸, we added the corresponding `S3:commentsOn` triple in I_1 . The set of users Ω_{I_1} corresponds to the set of user IDs having posted tweets, and we created links between users as follows. We assigned to every pair of users (a, b) a value $u_{\sim}(a, b) = t \cdot js_1(a, b) + (1 - t) \cdot js_2(a, b)$, where js_1, js_2 give the Jaccard similarities of the sets of keywords appearing in each user's posts, respectively, in each user's comments. Whenever this similarity was above a threshold, we created an edge of weight u_{\sim} between the two users. Through experiments on this dataset, we set the threshold to 0.1.

The instance I_2 uses data from Vodkaster, a French social network dedicated to movies. The data comprises *follower* relations between the users and a list of comments on the movies, in French, along with their author. Whenever user u follows user v we in-

⁸The corpus may contain a re-tweet of a tweet we do not capture; this is unavoidable unless one has access to the full Twitter history.

cluded `u vdk:follow v 1` in I_2 , where `vdk:follow` is a custom sub-property of `S3:social`. We translate the first comment on each film into a document; each additional comment was then considered a comment on the first. The text of each comment was stemmed, then each stemmed sentence was made a fragment of the comment.

The instance I_3 is based on Yelp [29], a crowd-sourced reviews website about businesses. This dataset contains a list of textual reviews of businesses, and the friend list of each user. As for I_2 , we considered that the first review of a business is commented on by the subsequent reviews of the same business. For each user u friend with user v , we added `u yelp:friend v 1` to I_3 , where `yelp:friend` is a `S3:social` subproperty modeling social Yelp connections. Reviews were also semantically enriched using DBPedia.

Table 4 shows the main features of the three quite different data instances. I_1 is by far the largest. I_2 was not matched with a knowledge base since its content is in French; I_2 and I_3 have no tags.

Queries For each instance we created workloads of 100 queries, based on three independent parameters:

- f , the keyword frequency: either *rare*, denoted ‘ $-$ ’ (among the 25% least frequent in the document set), or *common*, denoted ‘ $+$ ’ (among the 25% most frequent)
- l , the number of keywords in the query: 1 or 5
- k , the expected number of results: 5 or 10

This lead to a total of 8 workloads, identified by $qset_{f,l,k}$, for each dataset. To further analyze the impact of varying k , we added 10 more workloads for I_1 , where $f \in \{+, -\}$, $l = 1$, and $k \in [1, 5, 10, 50]$ (used in Figure 7). We stress here that injecting semantics in our workload queries, by means of keyword extensions (Definition 2.1), increased their size on average by 50%.

Systems Our algorithms were fully implemented in Python 2.7; the code has about 6K lines. We stored some data tables in PostgreSQL 9.3, while others were built in memory, as we explain shortly. All our experiments were performed on a 4 cores Intel Xeon E3-1230 V2 @3.30GHz with 16Go of RAM, running Debian 8.1.

No existing system directly compares with ours, as we are the first to consider fine-granularity content search with semantics in a social network. To get at least a rough performance comparison, we used the Java-based code provided by the authors of the top- k social search system described in [18], based on the UIT (user, item tag) model, and referred to as **TopkS** from now on. The data model of TopkS is rather basic, since its documents (*items*) have no internal structure nor semantics and tags have no semantic connection between them. Further, (*user, user, weight*) tuples reflect weighted links between users. TopkS computes a social score and a content-based score for each item; the overall item score is then $\alpha \times$ social score $+(1 - \alpha) \times$ content score, where α is a parameter of TopkS.

We adapted our instances into TopkS’s simpler data model. From I_1 , we created I'_1 as follows: (i) the relations between users were kept with their weight; (ii) every tweet was merged with all its retweets and replies into a single item, and (iii) every keyword k in the content of a tweet that is represented by item i posted by user u led to introducing the (user, item, tag) triple (u, i, k) . To obtain I'_2 and I'_3 , each movie or business becomes an item, each word extracted from a review leads to a (user, item, tag) tuple.

5.2 Implementation and optimizations

We briefly discuss our implementation, focusing on optimizations w.r.t. the conceptual description in Section 4.

The first optimization concerns the computation of *prox*, required for the score (Definition 3.5). While the score involves connections between documents and keywords found on any path, in practice $S3_k$ explores paths (and nodes) increasingly far from

Figure 5: Query answering times on I_1 (Twitter).

the seeker, and stores such paths in *borderPath*, which may grow very large and hurt performance. To avoid storing *borderPath*, we compute for each explored vertex v the weighted sum over all paths of length n from the seeker to this vertex:

$$borderProx(v, n) = \sum_{p \in u \rightsquigarrow v, |p|=n} \frac{\overline{prox}(p)}{\gamma^n}$$

and compute *prox* directly based on this value.

Furthermore, Algorithm `GetDocuments` considers documents reachable from x through edges labeled `S3:partOf`, `S3:commentsOn`, `S3:commentsOn,S3:hasSubject` or `S3:hasSubject`. Reachability by such edges defines a *partition* of the documents into *connected components*. Further, by construction of *con* tuples (Section 3.2), connections carry over from one fragment to another, across such edges. Thus, a fragment matches the query keywords iff its component matches it, leading to an efficient pruning procedure: we compute and store the partitions, and test that each keyword (or extension thereof) is present in every component (instead of fragment). Partition maintenance is easy when documents and tags are added, and more expensive for deletions, but luckily these are rarer.

The query answering algorithm creates in RAM the *allProx* table and two sparse matrices, computed only once: *distance*, encoding the graph of network edges in I (accounting for the vertical neighborhood), and *component*, storing the component of each fragment or tag. Thus, Algorithm 3, which computes *allProx* and finds new components to explore, relies on efficient matrix and vector operations. For instance, the new distance vector *borderProx* w.r.t. the seeker at step $n + 1$ is obtained by multiplying the distance matrix with the previous distance vector from step n . The documents and the RDF graph, on the other hand are not stored in RAM, and are queried using a PostgreSQL database.

The search algorithm can be *parallelized* in two ways. First, within an iteration, we discover new documents in different components in parallel. Second, when *borderProx* is available in the current iteration, we can start computing the next *borderProx* using the distance matrix. More precisely, Algorithm 3 (`ExploreStep`) can be seen as consisting of two main blocks: (i) computing the new *borderProx* using the (fixed) distance matrix and the previous *borderProx* (lines 1-12 except line 10); (ii) computing *allProx* using the new *borderProx* and the previous *allProx* (lines 13-16) plus the call to `GetDocuments` (line 10). The latter algorithm consists of two parts: (iii) identifying the newly discovered components, respectively (iv) testing the documents they contain. We used 8 concurrent threads, each running a task of one of the forms (i)-(iv), above, and synchronized them with a custom

Figure 6: Query answering times on I_3 (Yelp).

scheduler. This reduced the query answering time on average by a factor of 2.

5.3 Query answering times

Figures 5 and 6 show the running times of $S3_k$ on the I_1 and I_3 instances; the results on the smaller instance I_2 are similar [3]. We used different values of the γ social proximity damping factor (Section 3.4) and the α parameter of TopkS. For each workload, we plot the average time (over its 100 queries). *All runs terminated by reaching the threshold-based stop condition* (Algorithm 2).

A first thing to notice is that while all running times are comparable, TopkS runs consistently faster. This is mostly due to the different proximity functions: our *prox*, computed from all possible paths, has a much broader scope than TopkS, which explores and uses only one (shortest) path. In turn, as we show later, we return a significantly *different* set of results, due to *prox*'s broader scope and to considering document structure and semantics.

Decreasing the γ in $S3_k$ reduces the running time. This is expected, as γ gives more weight to nodes far from the seeker, whose exploration is costly. Similarly, *increasing* α in TopkS forces to look further in the graph, and affects negatively its performance.

The influence of k is more subtle. When the number of candidates is low and the exploration of the graph is not too costly, higher k values allow to include most candidates among the k highest-scoring ones. This reduces the exploration needed to refine their bounds enough to clarify their relative ranking. In contrast, if the number of candidates is important and the exploration costly, a small k value significantly simplifies the work. This can be seen in Figure 7 where, with frequent keywords, increasing k does not affect the 3 fastest quartiles but significantly slows down the slowest quartile, since the algorithm has to look further in the graph.

The same figure also shows that rare-keyword workloads (whose labels start by $-$) are faster to evaluate than the frequent-keyword ones (workload labels starting with $+$). This is because finding rare keywords tends to require exploring longer paths. Social damping at the end of such paths is high, allowing to decide that possible matches found even farther from the seeker will not make it into the top- k . In contrast, matches for frequent keywords are found soon, while it is still possible that nearby exploration may significantly change their relative scores. In this case, more search and computations are needed before the top- k elements are identified.

Figure 7: Query answering times on I_1 when varying k .

Measure \ Instance	I_1	I_2	I_3
Graph reachability	12%	23%	41%
Semantic reachability	83%	100%	78%
L_1	8%	10%	4%
Intersection size	13.7%	18.4%	5.6%

Figure 8: Relations between $S3_k$ and TopkS answers.

5.4 Qualitative comparison

We compare now the answers of our $S3_k$ algorithm and those of TopkS from a *qualitative* angle. $S3_k$ follows links between documents to access further content, while TopkS does not; we term *graph reachability* the fraction of candidates reached by our algorithm which are not reachable by the TopkS search. Further, while $S3_k$ takes into account semantics by means of semantic extension (Definition 2.1), TopkS only relies on the query keywords. We call *semantic reachability* the ratio between the number of candidates examined by an algorithm *without* expanding the query, and the number of candidates examined *with* query expansion. Observe that some $S3_k$ candidates may be ignored by TopkS due to the latter's lack of support for *both* semantics and connections between documents. Finally, we report two measures of distance between the results of the two algorithms. The first is the *intersection size* i.e., the fraction of $S3_k$ results that TopkS also returned. The second, L_1 , is based on Spearman's well-known *foot rule* distance between lists, defined as:

$$L_1(\tau_1, \tau_2) = 2(k - |\tau_1 \cap \tau_2|)(k+1) + \sum_{i \in \tau_1 \cap \tau_2} |\tau_1(i) - \tau_2(i)| - \sum_{\substack{\tau \in \{\tau_1, \tau_2\} \\ i \in \tau \setminus (\tau_1 \cap \tau_2)}} \tau(i)$$

where $\tau_j(i)$ is the rank of item i in the list τ_j .

The averages of these 4 measures over the 8 workloads on each instance appear in Figure 8. The ratios are low, and show that different candidates translate in different answers (the low L_1 stands witness for this). Few $S3_k$ results can be attained by an algorithm such as TopkS, which ignores semantics and relies only on the shortest path between the seeker and a given candidate.

5.5 Experiment conclusion

Our experiments have demonstrated first the ability of the $S3$ data model to *capture very different social applications*, and to query them meaningfully, accounting for their structure and enriching them with semantics. Second, we have shown that $S3_k$ *query answering can be quite efficient*, even though considering all paths between the seeker and a candidate answer slows it down

w.r.t. simpler algorithms, which rely on a shortest-path model. We have experimentally verified the expected impact of the social damping factor γ and of the result size k on running time. Third, and most importantly, we have shown that taking into account in the relevance model the social, structured, and semantic aspects of the instance bring a *qualitative gain*, enabling meaningful results that would not have been reachable otherwise.

6. RELATED WORK

Prior work on *keyword search in databases* spreads over different research directions:

Top-k search in a social environment uses UIT models [18, 21, 30] we outlined in Section 1. Top-k query results are found based on a score function accounting for the presence of each keyword in the tags of a candidate item, and a simple social distance based on the length of the social edge paths; query answering algorithms are inspired from the general top-k framework of [8]. As documents are considered atomic, and relations between them are ignored, requirements **R1**, **R2** and **R4** are not met. Further, the lack of semantics also prevents **R5**. Recent developments tend to focus on performance and scalability, or the integration of more attributes such as locality or temporality [7, 16], without meeting the abovementioned requirements. Location and time can be added to generic scores but this is outside of the scope of this paper.

Semi-structured document retrieval based on keywords relies mostly on the *Least Common Ancestors* approach, by which a set of XML nodes containing the requested keywords are resolved into one result item, their common ancestor node [6, 23]. This field pioneered by [11], encompassed by our model, generalizes LCA constraints but lacks both social and semantics, and thus meets only **R2**. Other recent developments in this area, including more flexible and comprehensive reasoning patterns, have been presented in [2] but have the same limitations. IR-style search in relational databases [12, 13] considers key-foreign key relationships between items, but ignores text structure, semantics, and social aspects.

Semantic search on full-text documents, either via RDF [15, 25] or a semantic similarity measure [24], allows to query interconnected, semantic rich unstructured textual documents or entities, thus meeting **R1**, **R5** and **R6**. Efforts to consider XML structure in such semantics-rich models [9] also enable **R2**.

Personalized IR in a social context adapts the answers to a user's query, taking into account her interests and those of her direct and indirect social connections [5]; this meets **R1** but not **R2** nor **R3**.

All the aforementioned models can be seen as partial views over the S_3 model we devised, and they could easily be transcribed into it modulo some minor variations; for instance, Facebook's GraphSearch [7] is a restricted form of SPARQL query one could ask over an S_3 instance. Slight adaptations may be needed for social contexts tolerating *similarity* between keywords that goes beyond the strict specialization relation (in RDF sense) we consider. We have hinted in Section 2 how this could be included.

7. CONCLUSION

We devised the S_3 data model for structured, semantic-rich content exchanged in social applications. We also provided the S_{3k} top-k keyword search algorithm, which takes into account the social, structural and semantical aspects of S_3 . Finally, we demonstrated the practical interest of our approach through experiments on three real social networks.

Next, we plan to extend S_{3k} to a massively parallel in-memory computing model to make it scale further. We also consider gen-

erating user-centric knowledge bases to be used in S_{3k} , to further adapt results to the user's semantic perspective.

ABSTRACT

Subgraph/supergraph queries although central to graph analytics, are costly as they entail the NP-Complete problem of subgraph isomorphism. We present a fresh solution, the novel principle of which is to acquire and utilize knowledge from the results of previously executed queries. Our approach, *i*GQ, encompasses two component subindexes to identify if a new query is a subgraph/supergraph of previously executed queries and stores related key information. *i*GQ comes with novel query processing and index space management algorithms, including graph replacement policies. The end result is a system that leads to significant reduction in the number of required subgraph isomorphism tests and speedups in query processing time. *i*GQ can be incorporated into any sub/supergraph query processing method and help improve performance. In fact, it is the only contribution that can speedup significantly both subgraph and supergraph query processing. We establish the principles of *i*GQ and formally prove its correctness. We have implemented *i*GQ and have incorporated it within three popular recent state of the art index-based graph query processing solutions. We evaluated its performance using real-world and synthetic graph datasets with different characteristics, and a number of query workloads, showcasing its benefits.

Keywords

Graph query processing, indexing, query result caching

1. INTRODUCTION

Graph structured data are prevalent in many modern big data applications, ranging from chemical, bioinformatics,

and other scientific datasets to social networking and social-based applications (such as recommendation systems). In biology, for example, there is a great need to model “structured interaction networks”. These abound when studying species, proteins, drugs, genes, and molecular and chemical compounds, etc. In these graphs, nodes can model species, genes, etc. and edges reflect relationships between them. Molecular compounds, consisting of atoms and their bonds, are naturally modeled as graphs. Ditto for social networks, where nodes refer to people and edges to their relationships.

Developing systems and algorithms that can store, manage, and provide analysis over large numbers of (potentially large) graphs is a formidable challenge. Already, there exist several very large graph datasets. For instance, the PubChem[34] chemical compound dataset contains more than 35 million graphs and ChEBI[11] (Chemical Entities of Biological Interest) dataset contains more than half a million graphs. Further applications extend to software development and debugging[27] and to similarity searching in medical datasets[32]. As a result, a large number of graph data management systems, optimised for handling graph data, have emerged (e.g., Neo4J[4], InfitGraph[20]). This is in addition to graph management systems designed by big data companies for their own purposes (e.g., Twitter’s FlockDB[38], Google’s Pregel[28]) and the list is continuously expanding. Hence, the demand for high performance data analytics in graph data systems is steadily increasing.

Central to graph analytics, is the need to locate patterns in dataset graphs. Informally, given a query graph, the system is called to identify which of the stored graphs in its dataset contain it (subgraph matching), or are contained in it (supergraph matching). This is a very costly operation as it entails the NP-Complete[14] problem of subgraph isomorphism and even its most popular solutions [9, 25, 39] are computationally very expensive. This problem is exacerbated when dealing with datasets storing large numbers of graphs, as the number of required subgraph isomorphism tests grows. Furthermore, performance deteriorates significantly with increasing graph sizes.

The key driver of our work is the realization that in many applications, it is natural to expect that queries submitted in the past share subgraph or supergraph relationships with queries of the future. As one example, consider chemical graph datasets, where queries use the graph representation of chemical entities. Such queries are naturally hierarchical: At the base, we see chemical elements. Then, there are graphs depicting chemical compounds (consisting of chemical elements), while there are also techniques to

create chemical compound clusters out of similar chemical compounds[34]. Similarly, in protein datasets there is also a hierarchy of queries for aminoacids, proteins, protein mixtures, proteins of uni-cell bacteria, all the way to those of multi-cell organisms. Finally, typical tools for social network analysis (SNA – e.g., Pajek[10]) provide the ability to produce graphs by filtering nodes and/or edges from other graphs. Using such graphs as queries in exploratory interactive SNA induces again the previous characteristic. For instance, consider the (query) graphs for analyzing friendship networks: such networks within the USA are subgraphs of friendship networks within North America, which in turn are subgraphs of the complete friendship network graph. The conclusion is that, in many applications, any query can itself be a subgraph or supergraph of a previously issued query. Up to now, this natural subgraph/supergraph relationship among queries has not been exploited.

2. PERSPECTIVES AND RELATED WORK

The problem of subgraph/supergraph query processing has been extensively studied. A prominent paradigm in the literature is the *filter then verify* paradigm. Essentially, this is an index-based class of methods. During indexing, the dataset graphs are reduced to their features (a *feature* being any substructure of a graph, be it path, tree, cycle, or arbitrary subgraph), which are inserted into an index structure (e.g., tree, trie, hash table, etc.). Given a query graph g , g is also decomposed into its features, following the same process as for dataset graphs. Then the index is searched for g 's features; for subgraph queries, the set of graphs that contain all of said features are returned, whereas for supergraph queries the returned set consists of graphs all of whose features are contained in g 's features. This set is called the *candidate set* and producing it constitutes the filtering stage of query processing.

All known algorithms guarantee that there will be no *false negatives*; that is, for subgraph (resp. supergraph) queries, all graphs in the dataset that can possibly contain (resp. are contained in) the query graph will be included in the candidate set. However, *false positives* are possible – not all graphs in the candidate set contain (resp. are contained in) the query graph. And herein lies the primary source of problems, since a subgraph subgraph isomorphism test must be performed against each graph in the candidate set, during the verification stage of query processing. The major focus of related work then is how to reduce the number of false positives, i.e., the number of unnecessary subgraph isomorphism tests.

Approaches in the literature can be classified along two dimensions: whether they employ (frequent) mining techniques or an exhaustive enumeration for the production of features, and based on the type of features of the dataset graphs they index (e.g., paths, trees, subgraphs). Note that exhaustive enumeration can yield huge indices and may take a prohibitively long time to do so. For this reason, all exhaustive enumeration approaches limit the size of features to a typically fairly small number of edges (i.e., 10 or less).

Mining-based approaches, both for supergraph queries ([5, 51, 46, 6, 52]) and subgraph queries (e.g., [41, 7, 52]) utilize techniques to mine for frequent (or *discriminating*, in [6]) (sub)graphs among the dataset graphs that are then indexed. Other mining-based approaches, like Tree+ Δ [49] and TreePi[45] mine for and index frequent trees. Last, Lin-

dex[43] and LWinindex[44] utilize the frequent mining algorithms of previous approaches, and are thus able to index and query several feature types. Typically such approaches tend to mine for more complex structures, which presents a trade-off between the complexity and time required for the indexing process vis-a-vis the potential for higher pruning power during query processing. However, numerous related performance studies [21, 12, 15, 17, 22] have shown that feature-mining approaches tend to be comparatively worse performers.

On the other hand, SING[12], GraphGrep[16] and GraphGrepSX[3] perform exhaustive enumeration, listing all paths of dataset graphs up to a certain path length. Similarly, CT-Index[22] indexes trees and cycles, whereas Grapes[15] indexes paths along with location information.

A different approach, which does not index features as above, is presented in gCode[53]. For each graph G in the graph dataset, gCode computes a signature per vertex of G (essentially reflecting the vertex's neighbourhood) and then computes a signature for G itself. The latter is a tree structure combining the signatures of all its vertices.

With respect to the verification stage, approaches also differ on how this is performed. In some works, verification is performed by applying any (exact) subgraph isomorphism algorithm of choice (see [25] for a detailed insightful comparative evaluation) after the filtering stage. Indeed, this can be the default choice for all approaches and there is a large variety of subgraph isomorphism algorithms available. Most such algorithms are influenced by Ullman's early work [39]. Arguably, the algorithm that is now the most widely used is the VF2[9] algorithm. Last, several approaches store and utilize location information in their index to achieve further filtering ([45, 12, 15]).

Recent performance studies [17, 21] have shown that CT-Index[22] and Grapes[15] are high performing approaches. CT-Index[22] is based on deriving canonical forms for the (tree, cycle) features of a graph G , to the fact that for trees and cycles finding string-based canonical forms can be done in linear time (unlike general graphs). These string representations of a graph's features are then hashed into a bitmap structure per graph G . Checking whether a query graph g can possibly be a subgraph of a graph G , can be done with simple bitwise operators between the bitmap of g and that of G (as supergraphs must contain all features of a subgraph). Last, its verification stage is then based on VF2.

Grapes[15] is designed to exploit parallelism available in multi-core machines. It exhaustively enumerates all paths (up to a maximum length), which are then inserted into a trie with their location information. This operation is performed in parallel by several threads, each of which works on a portion of the graph, producing its own trie, and subsequently all tries are merged together to form the path index of a graph. Grapes then computes (typically) small connected components of graphs in the candidate set, on which the verification (subgraph isomorphism test) is performed.

An insightful discussion and comparative performance evaluation of several indexing techniques for subgraph query processing (published prior to 2010) can be found in [17]. Furthermore, in [21] we presented a systematic performance and scalability study of several older as well as current state-of-the-art index-based approaches for subgraph query processing. We are not aware of similar in-depth studies of solutions to supergraph query processing; however, [44] pro-

vides a concise overview of related approaches.

On a related note, recent work also deals with graph querying against historical graphs, identifying subgraphs enduring graph mutations over time [35], which can be viewed as a variation whereby graph snapshots in time can be viewed as different graphs. Also, the research community has recently started looking into subgraph queries against a single, very large graph consisting of possibly billions of nodes [36]. To accelerate the query processing, SPath [48] proposes a path-at-a-time fashion, which proves to be more efficient than traditional vertex-at-a-time methods, whereas [36] makes use of a memory cloud and [33, 1, 24] exploit MapReduce. In this subgraph querying problem for the single large graph setting, the goal is to expedite the subgraph isomorphism itself, whereas in the setting with many dataset graphs, the target of subgraph querying problem is to minimize the number of isomorphism tests that need to be performed. Our work focuses on the latter setting and leaves for future work the application of our ideas to the former setting.

There has also been considerable work on approximate graph pattern matching. Relevant techniques (e.g., [22, 18, 37, 40, 42, 47, 50, 33, 13]) perform subgraph matching with support for wildcards and/or approximate matches. These solutions are not directly related to our work, as we expedite exact index-based subgraph/supergraph query processing.

Caching of the results of path/tree queries has been explored in XML databases [26, 2, 29]. The problem we focus on is considerably different, as the queries we deal with are in the form of graphs (not just paths/trees), thus entailing the NP-Complete problem of subgraph isomorphism. Furthermore, in our setting queries retrieve stored graphs that contain the query graph (subgraph queries) or are contained in it (supergraph queries), and we exploit both supergraph and subgraph relationships among queries themselves, as opposed to only subsumption (i.e., supergraph) relationships. Moreover, our graph replacement policy also takes into account the subgraph isomorphism costs, as opposed to just the size or popularity of cached queries.

Last, [23] presents a cache for targeted historical queries against a large social graph. In this case, each query is centered around a uniquely identified node in the social graph, and the objective is to avoid maintaining and/or reconstructing complete snapshots of the social graph, but to instead use a set of static “views” – i.e., snapshots of neighborhoods of nodes – to rewrite incoming queries. [23] does not deal with subgraph/supergraph query processing; rather, the nature of the queries means that containment can be decided by simply measuring the distance of the central query node to the center of each view, while also taking into account the diameter of these two graphs. Furthermore, the authors do not provide a cache replacement strategy, but rather an algorithm to compute the optimal cache contents given a set of queries. *iGQ* could well be used to both generalise and expedite query processing in [23].

2.1 The *iGQ* Perspective

In this work we offer a new perspective and a strategy for improving subgraph/supergraph query processing performance and scalability. Our approach rests on the following three observations: First, in related works there exists an implicit assumption that graph queries will be similarly structured to the dataset graphs. In general this is not guaranteed to hold (e.g., in exploratory analytics), and when

query graphs have no match in the dataset graphs, query processing cannot benefit at all from indexes that are solely constructed on dataset graphs. Second, even when query graphs have matches against dataset graphs, the system performs expensive computations during query processing and simply throws away all (painstakingly and laboriously) derived knowledge (i.e., previous querying result). Third, the success of known approaches depends on and exploits the fact that dataset graphs share features (e.g., when mining for frequent features) and/or that dataset graph features contain or are contained in other graph features (e.g., when using tries to index dataset graph features). However, they completely fail to investigate and exploit such similarities between query graphs.

As mentioned, it is natural in many applications for new queries to bear subgraph/supergraph relationships with previously issued queries. Our efforts in this work centre on exploiting this characteristic to further improve the performance of query processing. Therefore, instead of “mining” only the stored graphs and creating relevant indexes on them, we also “mine” *query graphs* and accumulate the knowledge produced by the system when running queries, creating a *query index* in addition to the *dataset index*. Our insights identify which is the relevant accumulated knowledge and how to exploit it during query processing in order to further reduce the number of subgraph isomorphism tests. *iGQ* can accommodate any proposed index for sub or supergraph query processing and help expedite both query types.

2.2 Contributions

The contributions of this work are that we:

- Provide a new perspective to the problem of subgraph/supergraph query processing, with insights as to how the work performed by the system when executing queries can be appropriately managed to improve the performance of future queries.
- Detail the *iGQ* approach, based on a query index structure and associated query processing algorithms, which can reduce the number of isomorphism tests performed during query processing.
- Present the *iGQ* framework, showing how to incorporate *iGQ* within existing approaches, and the two *iGQ* components: a subgraph query index and a supergraph query index. The subgraph index of *iGQ* can be based on any existing subgraph index (over query graphs, not dataset graphs). The supergraph index on the other hand is a new index to swiftly determine supergraph status between new and previous queries.
- Address the issue of index space management, providing mechanisms for index updates and a graph replacement policy, deciding contents of query index.
- Implement *iGQ*, incorporate it within three popular approaches for graph query processing, and provide experimental results using real-world datasets and a number of query workloads, showcasing *iGQ*’s benefits against competitive state of the art methods.

3. PROBLEM FORMULATION

We consider undirected labeled graphs. For simplicity, we assume that only vertices have labels; all our results straightforwardly generalize to graphs with edge labels.

DEFINITION 1. A labeled graph $G = (V, E, l)$ consists of

Figure 1: Dominance of the Verification Time on the Overall Query Processing Time of Three Subgraph Querying Algorithms on Two Different Real-world Graph Datasets

a set of vertices $V(G)$ and edges $E(G) = \{(u, v), u \in V, v \in V\}$, and a function $l : V \rightarrow U$, where U is the label set, defining the domain of labels of vertices.

A sequence of vertices (v_0, \dots, v_n) s.t. $\exists (v_i, v_{i+1}) \in E$, constitutes a path of length n . A simple path is a path where no vertices are repeated. A cycle is a path of length $n > 1$, where $v_0 = v_n$. A simple cycle is a cycle with no repeated vertices (other than v_0 and v_n). A connected graph is one where there exists a path between any pair of its vertices.

DEFINITION 2. A graph $G_i = (V_i, E_i, l_i)$ is subgraph-isomorphic to a graph $G_j = (V_j, E_j, l_j)$, (by abuse of notation) denoted by $G_i \subseteq G_j$, when there exists an injection $\phi : V_i \rightarrow V_j$, such that $\forall (u, v) \in E_i, u, v \in V_i \Rightarrow (\phi(u), \phi(v)) \in E_j$ and $\forall u \in V_i, l_i(u) = l_j(\phi(u))$.

Informally, there is a subgraph isomorphism $G_i \subseteq G_j$ if G_j contains a subgraph that is isomorphic to G_i . In this case, we say that G_i is a subgraph of (or contained in) G_j , or inversely that G_j is a supergraph of (contains) G_i (denoted by $G_j \supseteq G_i$).

DEFINITION 3. The subgraph querying problem entails a set $D = \{G_1, \dots, G_n\}$ containing n graphs, and a query graph g , and determines all graphs $G_i \in D$ such that $g \subseteq G_i$.

DEFINITION 4. The supergraph querying problem entails a set $D = \{G_1, \dots, G_n\}$ containing n graphs, and a query graph g , and determines all graphs $G_i \in D$ such that $g \supseteq G_i$.

The i GQ index, \mathbb{I} , will be called to index the features of query graphs; then we shall say that query graph g is indexed by i GQ and (by abuse of notation) denote it by $g \in \mathbb{I}$. We denote with $\mathbb{I}_{sub}(g)$ all query graphs currently contained in \mathbb{I} that are supergraphs of g (answers to g , if g was a subgraph query); i.e., $\mathbb{I}_{sub}(g) = \{G \in \mathbb{I} \mid g \subseteq G\}$. Similarly, we denote with $\mathbb{I}_{super}(g)$ all query graphs currently contained in \mathbb{I} that are subgraphs of g (answers to g , if g was a supergraph query); i.e., $\mathbb{I}_{super}(g) = \{G \in \mathbb{I} \mid g \supseteq G\}$.

4. iGQ PRINCIPLES

We firstly discuss our findings from experiments we ran regarding the major performance obstacles we need to overcome if we are to bring about further query processing time reductions. Subsequently, we present the i GQ framework, followed by an explanation of how the components of i GQ are utilized for further performance improvements, and related formal proofs of correctness. As mentioned, so far related work has not considered benefiting from the execution of previous queries. Thus, despite devoting a lot of resources to such queries, the results derived cannot be put to good use to improve performance of future subgraph queries.

Figure 2: Average Number of Candidates, Answer Set Size, and False Positives in the AIDS Dataset

4.1 Insights

We report on the fundamentals of the performance of three state of the art approaches, GraphGrepSX[3] (GGSX), Grapes[15], and CT-Index[22], over three real datasets and one synthetic dataset with different characteristics. These characteristics will be presented in detail in the experimental evaluation section. Briefly, AIDS represents a graph DB consisting of 40,000 very small, sparse graphs, while PDBS is a graph dataset containing 600 large graphs. Please note that the way the queries were generated is standard among related work [15, 22].

Subgraph Query Performance: Where Does Time Go?

There are two key components of the overall query processing time: filtering time (to process the index and produce the candidate set) and verification time (to perform the verification of all candidate graphs). Fig. 1 shows what percentage of the total query processing time is attributed to each component.

The dominance of the verification step is clear. This holds across the three different approaches that employ different indexing methods and utilize different strategies for cutting down the cost of subgraph isomorphism. Recall that subgraph isomorphism performance is highly sensitive to the size of both the input graph and the stored graph. Hence, we would expect that for smaller stored graphs (as in the AIDS dataset) the verification step would be much faster. Notably, however, even when graphs are very small, the verification step is the biggest performance inhibitor and as graphs become larger (e.g., PDBS) the verification step becomes increasingly responsible for nearly the total query processing time. Of course, given the NP-Completeness of subgraph isomorphism, one would expect that verification would dominate, especially for large graphs. But the fact that even with very small graphs this holds is noteworthy.

Filtering Power: Is It Good Enough?

The second fundamental point pertains to how one can reduce the verification cost. Related works highlight that their approaches prove to be very powerful in terms of filtering out the vast majority of DB graphs. In Figures 2 and 3 we show our results with respect to the average size of candidate sets and of the answer set, as well as the average number of false positives for the AIDS and PDBS datasets.

First, note that different algorithms behave differently in different datasets (e.g., Grapes significantly outperforms CT-Index in PDBS while the reverse holds for AIDS). Second, note that despite the powerful filtering of an approach, when the DB contains a large number of graphs (see Figure 2) in absolute numbers, there is a very large number of unnecessary subgraph isomorphism tests (i.e., false positives)

Figure 3: Average Number of Candidates, Answer Set Size, and False Positives in the PDBS Dataset

that is required. The above two combined imply that even the best algorithm will suffer from a large number of unnecessary subgraph isomorphism tests under some datasets.

Turning our attention to Figure 3 we see that for DBs with medium to small number of graphs, the high filtering power can indeed result in requiring only a relatively small number of subgraph isomorphism tests. However, considerable percentages of false positives can appear in the candidate sets of even top-performing algorithms; e.g., CT-Index, which exhibited the best filtering in the AIDS dataset, has an almost 50% false positive ratio in the PDBS dataset. Furthermore, not all subgraph isomorphism tests for the graphs in the candidate set are equally costly. As the cost of subgraph isomorphism testing depends on the size of the graph, the larger graphs in the candidate set contribute a much greater proportion of the total cost of the verification step. Note that, naturally, false positive graphs tend to be the largest graphs in the DB, since these have a higher probability to contain all features of query graphs.

Note that we placed emphasis on the number of unnecessary subgraph isomorphism tests (i.e., the false positives), as we can improve filtering further by reducing this number. However, this is not the only source of possible improvements. As we shall show later, *iGQ* can improve on the number of subgraph isomorphism tests even beyond this, by exploiting knowledge gathered during query execution.

The insights that can be drawn are as follows:

- Despite the fact that state of the art techniques (based on indexing features of DB graphs) can enjoy high filtering capacity, there is still large room for improvement, as even the best approaches may perform large numbers of unnecessary subgraph isomorphism tests.
- Improving further the filtering power of approaches can significantly improve query processing time, as this will reduce the number of subgraph isomorphism tests, which dominates the overall querying time.
- Even approaches that are purported to enjoy great filtering powers, can behave much more poorly under different datasets.
- Unnecessary subgraph isomorphism tests are not solely caused by false positives; even graphs in the candidate set that are true positives can be unnecessarily tested if the system fails to exploit this knowledge (accrued by previous query executions).

4.2 The *iGQ* Framework

iGQ aims to augment the functionality and benefits offered by any one of the subgraph and/or supergraph indexing methods in the literature. Let us call the chosen method \mathbb{M} . The *iGQ* framework consists of method \mathbb{M} and the two components of \mathbb{I} , \mathbb{I}_{sub} and \mathbb{I}_{super} . For the sake of simplicity, we shall first describe the operation of *iGQ* when \mathbb{M} is a

method for subgraph query processing (denoted \mathbb{M}_{sub}). Initially, method \mathbb{M}_{sub} builds its graph dataset index as per usual. The *iGQ* index, \mathbb{I} , starts off empty; it is then populated as queries arrive and are executed by \mathbb{M}_{sub} .

Upon the arrival of a query g , the query processing process is parallelized. One thread uses method \mathbb{M}_{sub} 's algorithms and indexing structure to breakdown the query graph into its features, and uses its index to produce a candidate set of graphs, $CS(g)$, as usual. Additionally, \mathbb{I} will obtain as many of the intermediate and final results from method \mathbb{M} 's execution as possible; e.g., it will obtain the features of the query graph, to be compared to those stored in \mathbb{I} (from previously-executed queries). At this point, two separate threads will be created: one will check whether the query graph is a subgraph of previous query graphs and the other will check whether it is a supergraph of previous query graphs. These cases yield different opportunities for optimization and are discussed separately below.

In the following we proceed to describe the function of each component of the *iGQ* framework and how it is all brought together. For the formal proofs of correctness that follow, for simplicity, we make the following assumptions.

Assumptions. The *iGQ* index components, \mathbb{I}_{sub} and \mathbb{I}_{super} work correctly. That is:

$$G \in \mathbb{I}_{sub}(g) \Rightarrow g \subseteq G \quad (1)$$

and

$$G \in \mathbb{I}_{super}(g) \Rightarrow g \supseteq G \quad (2)$$

We will prove that these assumptions hold in sections 6.1 and 6.2.

4.2.1 The Subgraph Case: \mathbb{I}_{sub}

This case occurs when a new query g is a subgraph of a previous query G . When G was executed by the system, the \mathbb{I}_{sub} component of *iGQ* indexed G 's features. Additionally, *iGQ* stored the results computed by \mathbb{M}_{sub} for G .

Fig. 4 depicts an example for the subgraph case of *iGQ*. A new query g is "sent" to method \mathbb{M}_{sub} 's graph index, producing a candidate set, $CS(g)$, which in this case contains the four graphs $\{g_1, g_2, g_3, g_4\}$. Similarly, g is "sent" to the *iGQ* subgraph component, \mathbb{I}_{sub} , from where it is determined that there exists a previous query G , such that $g \subseteq G$. *iGQ* then retrieves the answer set, $Answer(G)$ (previously produced by method \mathbb{M}_{sub} and indexed by \mathbb{I}_{sub}); in this case, $Answer(G) = \{g_1, g_2\}$. The reasoning then proceeds as follows. Consider graph $g_1 \in CS(g)$. Since from \mathbb{I}_{sub} it has been concluded that $g \subseteq G$ and from the answer set of G we know that $G \subseteq g_1$, it necessarily follows that $g \subseteq g_1$. Similarly, we conclude that $g \subseteq g_2$. Hence, there is no point in testing g for subgraph isomorphism against g_1 or g_2 , as the answer is already known. Therefore, one can safely subtract graphs g_1, g_2 from \mathbb{M}_{sub} 's candidate set, and test only the remaining graphs (reducing the number of subgraph isomorphism tests in this example by 50%). After the verification stage, g_1, g_2 are added to the final answer set.

In the general case, g may be a subgraph of multiple previous query graphs G_i in \mathbb{I}_{sub} . Following the above reasoning, we can safely remove from $CS(g)$ all graphs appearing in the answer sets of all query graphs G_i , as they are bound to be supergraphs of g ; that is, the set of graphs submitted by

Figure 4: iGQ Processing of a Subgraph Query in the Subgraph Case

iGQ for subgraph isomorphism testing is given by:

$$CS_{sub}(g) = CS(g) \setminus \bigcup_{G_i \in \mathbb{I}_{sub}(g)} Answer(G_i) \quad (3)$$

Finally, if $Answer_{sub}(g)$ is the subset of graphs in $CS_{sub}(g)$ verified to be containing g through subgraph isomorphism testing, the final answer set for query g will be:

$$Answer(g) = Answer_{sub}(g) \cup \bigcup_{G_i \in \mathbb{I}_{sub}(g)} Answer(G_i) \quad (4)$$

LEMMA 1. *The iGQ answer in the subgraph case does not contain false positives.*

PROOF. Assume that a false positive was produced by iGQ; particularly, consider the first ever false positive produced by \mathbb{I}_{sub} , i.e., for some query g , $\exists G_{FP}$ such that $g \not\subseteq G_{FP}$ and $G_{FP} \in Answer(g)$. Note that G_{FP} cannot be in $Answer_{sub}(g)$, as the latter contains only those graphs from $CS_{sub}(g)$ that have been verified to be supergraphs of g after passing the subgraph isomorphism test, and hence $g \not\subseteq G_{FP} \Rightarrow G_{FP} \notin Answer_{sub}(g)$. Therefore, by formula (4), $G_{FP} \in Answer(g) \Rightarrow \exists G$ such that $G \in \mathbb{I}_{sub}(g)$ and $G_{FP} \in Answer(G)$. But (by formula (1)) $G \in \mathbb{I}_{sub}(g) \Rightarrow g \subseteq G$, and $G_{FP} \in Answer(G) \Rightarrow G \subseteq G_{FP}$. Thus $g \subseteq G_{FP}$ (a contradiction). \square

LEMMA 2. *iGQ in the subgraph case does not introduce false negatives.*

PROOF. Assume that a false negative was produced by iGQ; particularly, consider the first ever false negative produced by \mathbb{I}_{sub} , i.e., for some query g , $\exists G_{FN}$ such that $g \subseteq G_{FN}$ and $G_{FN} \notin Answer(g)$. As method \mathbb{M}_{sub} is assumed to be correct, it cannot produce any false negatives when processing query g , hence $g \subseteq G_{FN} \Rightarrow G_{FN} \in CS(g)$. Then, the only possibility for error is that G_{FN} was removed using formula (3); i.e., $G_{FN} \notin CS_{sub}(g)$. That implies that $\exists G$ such that $G \in \mathbb{I}_{sub}(g)$ and $G_{FN} \in Answer(G)$. But then, by formula (4), G_{FN} will be added to $Answer_{sub}(g)$ and thus $G_{FN} \in Answer(g)$ (a contradiction). \square

THEOREM 1. *The iGQ answer in the subgraph case of query processing is correct.*

PROOF. There are only two possibilities for error; iGQ can produce false negatives or false positives. The theorem then follows straightforwardly from Lemmas 1 and 2. \square

4.2.2 The Supergraph Case: \mathbb{I}_{super}

This case occurs when a new query g is a supergraph of a previous query G . Fig. 5 depicts an example for the supergraph case of iGQ. Again, the subgraph query processing method \mathbb{M}_{sub} produces a candidate set, $CS(g)$ that, say, contains four graphs $\{g_1, g_2, g_3, g_4\}$. Running g through \mathbb{I}_{super} ,

Figure 5: iGQ Processing of a Subgraph Query in the Supergraph Case

it is determined that there exists a previous query graph G such that $G \subseteq g$. Also \mathbb{I}_{super} supplies the stored answer set for G , $Answer(G) = \{g_1, g_{20}\}$.

The reasoning then proceeds as follows. Consider graph $g_2 \in CS(g)$. We know from \mathbb{I}_{super} that $g_2 \notin Answer(G)$. Now, if $g \subseteq g_2$ were to indeed be true, since $G \subseteq g$, then it must also hold that $G \subseteq g_2$; that is, $Answer(G)$ would have to contain g_2 as well, which is a contradiction. Therefore, it is safe to conclude that $g \not\subseteq g_2$ and thus g_2 can be safely removed from $CS(g)$. Similarly, we can also safely remove graphs g_3, g_4 from $CS(g)$, reducing in this case the number of required subgraph isomorphism tests by 75%. Thus, only g_1 needs to be isomorphism-tested in this example.

In the general case, g may be a supergraph of multiple previous query graphs G_i in \mathbb{I}_{super} . By the above reasoning, only those graphs appearing in the answer sets of all queries G_i may actually be supergraphs of g ; thus the set of graphs submitted by iGQ for subgraph isomorphism testing is:

$$CS_{super}(g) = CS(g) \cap \bigcap_{G_i \in \mathbb{I}_{super}(g)} Answer(G_i) \quad (5)$$

The final answer produced for query g by iGQ, $Answer(g)$, will be the subset of graphs in $CS_{super}(g)$ that have been verified by the subgraph isomorphism test.

LEMMA 3. *The iGQ answer in the supergraph case does not contain false positives.*

PROOF. This trivially follows by construction as all graphs in $Answer(g)$ have passed through subgraph isomorphism testing at the final stage of processing. \square

LEMMA 4. *The iGQ answer in the supergraph case does not introduce false negatives.*

PROOF. Assume false negatives are possible and consider the first ever false negative produced by \mathbb{I}_{super} ; i.e., for some query g , $\exists G_{FN}$ such that $g \subseteq G_{FN}$ and $G_{FN} \notin Answer(g)$. Method \mathbb{M}_{sub} does not produce in its candidate set any false negatives (as will be formally proven shortly), hence $G_{FN} \in CS(g)$. Then, the only possibility for error is for iGQ to have removed graph G_{FN} from $CS_{super}(g)$ with formula (5). This implies that $\exists G$ such that $G \in \mathbb{I}_{super}(g)$ and $G_{FN} \notin Answer(G)$. But since $G \in \mathbb{I}_{super}(g)$, by equation (2), $G \subseteq g$, and then $g \subseteq G_{FN} \Rightarrow G \subseteq G_{FN} \Rightarrow G_{FN} \in Answer(G)$ (a contradiction). \square

THEOREM 2. *The iGQ answer in the supergraph case of query processing is correct.*

PROOF. There are only two possibilities for error; iGQ can produce false negatives or false positives. The theorem then follows straightforwardly from Lemmas 3 and 4. \square

4.3 iGQ and Optimal Performance

There are two special cases that warrant further emphasis, since they introduce the greatest possible benefits.

First, note that iGQ can easily recognize the case where a new query, g , is exactly the same as a previous query contained in \mathbb{I} . Specifically, this holds when $\exists G \in \mathbb{I}$ such that $g \subseteq G$ or $g \supseteq G$, and g and G have the same number of nodes and edges. When this holds, since \mathbb{I} stores the result for G , we can return directly and completely avoid the subgraph isomorphism testing as the actual result for g is known! As the subgraph isomorphism test dominates the query execution time, this is expected to be a large performance improvement.

Second, consider the supergraph part of iGQ. If $\exists G \in \mathbb{I}_{super}(g)$ such that $G \subseteq g$ and $Answer(G) = \emptyset$, then we can completely omit the verification stage again: If there were a dataset graph G' such that $g \subseteq G'$, since $G \subseteq g$ we would conclude that $G \subseteq G'$, which necessarily implies that $G' \in Answer(G)$, which contradicts the fact that $Answer(G) = \emptyset$. Thus, no such graph G' can exist and it is safe to stop query processing at this stage.

4.4 iGQ and Supergraph Query Processing

As mentioned earlier, iGQ can expedite both subgraph and supergraph query processing. In the latter case, the components of iGQ (\mathbb{I}_{sub} , \mathbb{I}_{super}) remain unchanged, but the handling of the return answer sets is the exact inverse of what happens for subgraph queries. Briefly, given a supergraph query processing method \mathbb{M}_{super} and a supergraph query g , the union of the answer sets of graphs in $\mathbb{I}_{super}(g)$ are removed from $CS_{super}(g)$ and added to $Answer_{super}(g)$ to produce the final answer, and the graphs not appearing in the intersection of the answer sets of graphs in $\mathbb{I}_{sub}(g)$ are completely subtracted from $CS_{sub}(g)$. Also, the first optimal case mentioned above still holds, but the second optimal case is inversed with the processing terminating when $\exists G \in \mathbb{I}_{sub}(g)$ such that $Answer(G) = \emptyset$. The intuition behind this design and the proof of correctness of iGQ for supergraph query processing, follow the same reasoning as above and are omitted for space reasons. The elegance afforded by the double use of iGQ is unique.

5. iGQ INDEX SPACE MANAGEMENT

As queries arrive continuously and the space to store \mathbb{I} is finite, iGQ requires methods for (i) efficiently handling this space and (ii) ensuring that it is best utilized, keeping those query graphs that increase its performance impact.

5.1 iGQ Graph Replacement Policy

Our replacement policy differs fundamentally from standard replacement policies: Unlike traditional cache replacement, whereby replacing a page or a file block saves one IO, different graphs in \mathbb{I} bring about different benefits, as is shown below. We identify three key principles.

Increase the use of iGQ index. \mathbb{I} should contain popular graphs; this is typical of all replacement algorithms. We define the popularity of a graph g as $P(g) = \frac{H(g)}{M(g)}$, where $H(g)$ is the number of times a graph $g \in \mathbb{I}$ has been found to be a subgraph or supergraph of query graphs (*hit*), and $M(g)$ is the total number of all queries processed since g was added to the iGQ index. In essence, this models the fraction of queries affected over time by g being in \mathbb{I} .

Reduce the number of subgraph isomorphism tests.

Ideal graphs for \mathbb{I} are graphs that bring about the greatest possible reductions in the number of executed subgraph isomorphism tests. Let $R(g)$ be the total number of graphs removed from the candidate sets of incoming queries because of g being in \mathbb{I} . Then this component is computed as $\frac{R(g)}{H(g)}$ – the per-*hit* average number of subgraph isomorphism tests alleviated by g .

Reduce the cost of each subgraph isomorphism test.

A graph $g \in \mathbb{I}$ is more desirable if it helps avoid subgraph isomorphism tests on the biggest graphs from \mathbb{M} 's CS . This is so since we also wish to remove from CS graphs with expensive subgraph isomorphism tests. We denote by $C(g)$ the total cost of the subgraph isomorphism tests alleviated as a result of g being in \mathbb{I} . In order to estimate this value, we extend the asymptotic complexity analysis of [8] to the case of subgraph isomorphism. Specifically, given graphs with L labels, graph g' with n nodes, and graph G_i with $N_i \geq n$ nodes, the cost $c(g', G_i)$ of subgraph isomorphism of g' against G_i is given by:

$$c(g', G_i) = \frac{N_i \times N_i!}{L^{n+1} \times (N_i - n)!}$$

$C(g)$ is then computed as the sum over all $c(g', G_i)$, for all g' whose $CS(g')$ was reduced by removing G_i as a result of g being in \mathbb{I} , and $\frac{C(g)}{R(g)}$ gives the average cost reduction per alleviated test.

Ideal graphs for \mathbb{I} are those that could help future queries as much as possible. To quantify such a contribution, we introduce the notion of graph *utility*, $U(g)$, defined as:

$$U(g) = \frac{H(g)}{M(g)} \times \frac{R(g)}{H(g)} \times \frac{C(g)}{R(g)} = \frac{C(g)}{M(g)}$$

That is, the utility of a graph g in iGQ is equal to the probability of g being used for an incoming query (i.e., being *hit*), times the average savings in number of subgraph isomorphism tests per such hit, times the average cost for a single subgraph isomorphism test. The replacement policy is then based on this, with the graph with the smallest $U(g)$ being evicted.

5.2 iGQ Index Maintenance Policy

For all graphs in \mathbb{I} we maintain the metadata mentioned above (i.e., $C(g), M(g)$). Additionally, we store the actual query graphs that are indexed by \mathbb{I} in a separate store coined \mathbb{I}_{graphs} . To facilitate index updates without interfering with query processing performance, we employ the concepts of *query window size*, W , and *cache size*, \mathcal{C} , with $W \leq \mathcal{C}$. As new graph queries arrive, they are processed as outlined above, update the metadata for graphs in \mathbb{I} , and are inserted into a temporary storage \mathbb{I}_{temp} . When W new queries have been processed, we consult the metadata to locate the W graphs in \mathbb{I} with the lowest utility values. The graph data for those graphs is removed from \mathbb{I}_{graphs} and replaced by the graphs in \mathbb{I}_{temp} . The latter is then emptied, and a “shadow” index, \mathbb{I}_{shadow} , is built over graphs in \mathbb{I}_{graphs} . Incoming queries keep being served by \mathbb{I} and updating its metadata. When the shadow indexing is over, \mathbb{I}_{shadow} replaces \mathbb{I} (with a pointer swap). Finally, metadata for graphs removed from \mathbb{I} is also removed from the metadata store ($C(g), M(g)$).

6. iGQ ALGORITHMS AND STRUCTURES

The proofs of correctness provided by the previous section, assume that \mathbb{I}_{sub} and \mathbb{I}_{super} provide correct results (recall formulas (1) and (2)). We shall now discuss the associated mechanisms and prove that they hold.

Algorithm 1 The Supergraph Index in iGQ

```
1: Input: Set  $\mathbb{Q}$  of (previous) queries  $g_1, g_2, \dots, g_n$ 
2: Output: Supergraph index of previous queries  $\mathbb{I}_{super}$ 
3:
4: Initialize  $\mathbb{I}_{super}$  to an empty TRIE
5: for all  $g_i \in \mathbb{Q}$  do
6:   Extract all features of  $g_i$  and insert them in set  $F(g_i)$ 
7:    $NF[g_i] = |F(g_i)|$ 
8:   for all features  $f \in F(g_i)$  do
9:      $o = \text{number of occurrences of } f \text{ in } g_i$ 
10:     $\mathbb{I}_{super}.insert(f, \{g_i, o\})$ 
11:   end for
12: end for
13: return  $\mathbb{I}_{super}$ 
```

6.1 Finding Supergraphs in \mathbb{I}_{sub}

This case represents a microcosm of our original problem, where instead of indexing and querying dataset graphs, we index and query previous query graphs. Hence, any approach from the related works can be adapted for this purpose. Actually, as *iGQ* can complement any existing approach, \mathbb{M}_{sub} , we can utilize \mathbb{M}_{sub} 's method for subgraph query processing for the subgraph case of *iGQ*, or any other method appropriate for *iGQ*'s special characteristics (i.e., relatively small set of small graphs). Note that the assumed correct method \mathbb{M}_{sub} precludes false negatives and subgraph isomorphism testing of all candidates precludes false positives. Hence, formula (1)'s assumption is trivially satisfied.

6.2 Finding Subgraphs in \mathbb{I}_{super}

The problem of supergraph query processing has also received some attention (e.g., in [5, 44, 46, 6, 51]). In principle, any of these algorithms can be utilized for the task at hand within *iGQ*. However, we choose to propose a new approach, which is efficient yet simple and avoids the complexities and overheads involved in the above general approaches. The point is that we want a method for supergraph query processing that can easily fit within the framework of *iGQ* and perform both subgraph and supergraph query indexing and processing. Algorithm 1 shows how \mathbb{I}_{super} is created. Briefly, \mathbb{I}_{super} is a trie, storing features of queries. For each feature f it stores a pair $\{g_i, o\}$ for each graph g_i in which f appears, where o is its number of occurrences in g_i . For each g_i it also stores the number of distinct features ($NF[g_i]$) it contains.

Algorithm 2 illustrates how \mathbb{I}_{super} identifies candidates CS that are potential subgraphs of query g . The idea is to find those graphs that contain *only* features included in the query graph g (lines 19–22; the check for $count(g_i)$ on line 20, ensures that all individual features of g_i are contained in g), and where for each such graph g_i a feature f occurs at most as many times as f occurs in g (line 12). Last, the graphs in CS are isomorphically tested to verify that $g_i \subseteq g$.

It is straightforward to see that no false negatives can exist in CS . Assume there is a false negative g_i such that $g_i \subseteq g$ and $g_i \notin CS$. Since $g_i \subseteq g$, any feature f in g_i appears no more times than f appears in g , thus g_i would be added to \mathbb{G} on every execution of line 12. As $g_i \subseteq g$, all of g_i 's features must appear in g . Thus, g_i would pass the if-clause at line 20 and be added to CS (contradiction). Moreover, subgraph isomorphism testing of all members of CS precludes false positives. Hence, formula (2)'s assumption holds.

Algorithm 2 Supergraph Query Processing in iGQ

```
1: Input: Query graph  $g$  and  $\mathbb{I}_{super}$ 
2: Output: Candidate set  $CS$  of potential subgraphs of  $g$ 
3:
4: Initialize multiset  $\mathbb{G} = \emptyset$ 
5: Extract all features of query graph  $g$ ,  $F(g)$ 
6: for all features  $f \in F(g)$  do
7:    $O[f, g] = \text{number of occurrences of } f \text{ in } g$ 
8: end for
9: for all features  $f \in F(g)$  do
10:  if  $f \in \mathbb{I}_{super}$  then
11:    for all  $\{g_i, o\} \in \mathbb{I}_{super}.get(f)$  do
12:      if  $o \leq O[f, g]$  then
13:         $\mathbb{G}.insert(g_i)$ 
14:      end if
15:    end for
16:  end if
17: end for
18: for all graphs  $g_i \in \mathbb{G}$  do
19:    $count(g_i) = \text{number of occurrences of } g_i \text{ in } \mathbb{G}$ 
20:   if  $count(g_i) == NF[g_i]$  then
21:      $CS.add(g_i)$ 
22:   end if
23: end for
24: return  $CS$ 
```

6.3 iGQ System Operation

Fig. 6 depicts the complete *iGQ* system operation when used to expedite a subgraph query processing method \mathbb{M}_{sub} . Please keep in mind, though, that *iGQ* can be integrated with any subgraph and/or supergraph querying method. Given a new subgraph query g :

1. The query is sent to three separate processing threads in parallel and also stored in the query *window*.
2. In the first thread, \mathbb{M}_{sub} uses its *Dataset Graph Index* to filter the dataset graphs and produce the candidate set $CS(g)$, as usual.
3. The remaining two threads perform filtering along the subgraph (section 4.2.1) and supergraph path (section 4.2.2). Their results are combined to prune $CS(g)$, based on formulae (3) and (5).
4. The resulting candidate set, $CS_{igq}(g)$, undergoes subgraph isomorphism testing to produce $Ans_{igq}(g)$.
5. Since this is for a subgraph query, the graphs pruned during processing along the subgraph path in step 3 are added to $Ans_{igq}(g)$ to produce the final answer set, $Answer(g)$ (see formula (4)).
6. Metadata maintained throughout the processing of g , including $Answer(g)$ and its subgraphs/supergraphs detected during step 3, are added to the metadata store, $Stat(iGQ_Graph)$.
7. If the query window is full, the system uses the above metadata to select appropriate cached graphs to evict. Said graphs are replaced by the graphs in the window.
8. Finally, the *iGQ* index is updated to reflect the new contents of the cache (section 5.2 details the maintenance of the *iGQ* index).

7. PERFORMANCE EVALUATION

We have implemented the *iGQ* algorithms and report on experiments evaluating its performance on the savings of

Figure 6: Operation of *iGQ* on Top of a Subgraph Query Processing Method M_{sub}

subgraph query processing time (supergraph query processing time is omitted for space reason) and on the number of subgraph isomorphism tests.

7.1 Experimental Setup

Experiments were run on a Dell R920 system (4 Intel Xeon(R) CPUs (15 cores each), 512GB RAM, 1TB disk), and on a cluster of four Dell R720's (each with 2 Intel Xeon(R) CPUs (8 cores each), 64GB RAM, 1TB disk).

Algorithms. In addition to our implementation of *iGQ* query processing, we also secured access to implementations of three recent high performing subgraph query processing methods, GraphGrepSX[3] (GGSX), Grapes[15], and CT-Index[22]. In addition to their competitive performance, these three methods represent interesting design decisions. GGSX indexes paths (up to a certain maximum length, equal to 4 in these experiments) and uses the VF2 subgraph isomorphism algorithm for its verification stage. Grapes, like GGSX, also indexes paths (of up to length of 4), but utilizes location information in the filtering stage to expedite the verification stage, essentially focusing only on connected components of the dataset graphs that may contain the query graph. CT-Index indexes trees (of maximum size 6), and cycles (of maximum size 8) in hash-based bitmap structures (4096-bit wide), and uses a modified VF2 for its verification stage.

The implementations for Grapes and GGSX were obtained from the corresponding project web sites[15, 3]. For Grapes, we present two alternatives, Grapes and Grapes(6), which use 1 and 6 threads respectively. For fairness, we altered the code of Grapes so to stop query processing when the first match was found, instead of looking for all matches of a query within each stored graph. For CT-Index we obtained the JAR file from one of the authors, which we then reverse-engineered to derive its code in Java. Subsequently, we integrated the *iGQ* algorithms of Section 4.2.1 within Grapes, CT-Index, and GGSX, yielding three different versions of *iGQ*, denoted as *iGQ_Grapes*, *iGQ_CT-Index*, and *iGQ_GGSX*. In this way, (i) we validate our claim that *iGQ* can be incorporated into existing approaches, and (ii) we show that it can introduce significant performance gains during subgraph query processing of any of these approaches.

Datasets. We have employed three real-world datasets and one synthetic dataset with different characteristics, outlined in Table 1. AIDS is the Antiviral Screen Dataset of the National Cancer Institute, containing topological structures of molecules [30]. PDBS[19] is a dataset of graphs representing DNA, RNA and proteins. As AIDS and PDBS contain typical but relatively sparse graphs, we have per-

dataset	unique vertex labels	graphs in dataset	average node degree	num. nodes per graph			num. edges per graph		
				avg	std.dev	max	avg	std.dev	max
AIDS	62	40,000	2.09	45	22	245	47	23	250
PDBS	10	600	2.13	2,939	3,217	16,431	3,064	3,264	16,781
PPI	46	20	9.23	4,943	2,717	10,186	26,667	26,361	89,674
Synthetic	20	1,000	19.52	892	417	7,135	7,991	5	8,007

Table 1: Characteristics of Datasets

formed further experiments on dense datasets, including the PPI dataset and a synthetic dataset. PPI[15] models large and dense protein interaction networks and consists of 20 graphs. We also used the generator provided by [7] to create a much larger number (1,000) of much denser graphs.

Query Workloads. Unfortunately, despite the availability of graph datasets, the community does not enjoy well established benchmarks and/or real-world query logs for these datasets. So all related works synthesize queries derived from components of the dataset graphs. We follow this established principle for generating our workloads, whereby queries are generated from the original dataset graphs as follows. There are 3 key probability distributions to consider here. The first governs how a graph is selected from the dataset graphs. The second governs how a node is selected within this graph. Given these, we produce 4 query workloads: *uni-uni*, *uni-zipf*, *zipf-uni*, and *zipf-zipf*, with, e.g., *zipf-uni* denoting that dataset graphs have a popularity (probability of being selected) following a Zipf distribution, while nodes within the selected graph have a popularity drawn from a uniform distribution. The probability density function of the Zipf distribution is given by: $p(x) = \frac{x^{-\alpha}}{\zeta(\alpha)}$, where ζ is the Riemann Zeta function[31]. The default value for α was 1.4 – we have also used $\alpha = 1.1$ representing a much smaller skew and $\alpha = 2.0$ representing a stronger skew (as a reference point, web page popularities follow a Zipf with $\alpha = 2.4$ [31]). The third governs the size of each graph query: query sizes are uniformly at random selected from 4, 8, 12, 16, 20 edges. Once a graph and a node within this graph have been selected, we then perform a BFS traversal of the latter's neighborhood, with unvisited edges of each traversed node included in the generated graph, until the desired query size is reached.

For AIDS and PDBS, we ran 3,000 queries for each experiment. The first W of these queries were used to warm-up the index. We then used the remaining queries to measure the times and candidate set sizes with and without *iGQ* for each algorithm. By default we use a cache size $C = 500$ and a batch window (and warm-up set) size $W = 100$ queries – we have also used $C = 1000, W = 200$ and $C = 1500, W = 300$ with a 5,000-query workload to test cache size impact. We

Figure 7: Speedup in Number of Subgraph Isomorphism Tests for AIDS

Figure 8: Speedup in Number of Subgraph Isomorphism Tests for PDBS

further tested *iGQ* against PPI and the synthetic dataset, in order to examine its performance under larger and denser graphs. In these cases, queries take 1-2 orders of magnitude more time to execute, hence for practical reasons we reduced the query workload to 500 queries. The batch window (and warm-up set) size were set to $W = 20$ queries, with cache sizes of $C = 100, 200, 300$ and Zipf skew $\alpha = 1.4, 2.0, 2.4$.

We report the speedup (reduction) achieved by *iGQ*, defined as the ratio of the average performance of the traditional method M over the average performance of *iGQ*, M , for the number of subgraph isomorphism tests and the query processing time.

7.2 Filtering Power Speedup

We first examine the *filtering power*, reflecting the speedup in the number of subgraph isomorphism tests performed. This metric facilitates a qualitative analysis of performance, independent of implementation and system details. Fig. 7 and 8 depict results for the AIDS and PDBS datasets respectively, across all four query workloads. The reduction in the number of subgraph isomorphism tests is evident (speedups of $5\times$ to $11\times$). Fig. 9 shows how Zipf skew α affects this metric for the PDBS dataset, using one of the fastest methods (Grapes(6)). Results for the AIDS dataset and the other algorithms are similar and omitted for space reasons. As expected, with more skewness come increased benefits by *iGQ*.

Fig. 10 focuses on speedup across queries grouped by size (e.g., Q4 groups queries with 4 edges). As *iGQ* does not maintain separate caches per query size, the various query groups compete for the same space. Thus, some of them may seem to exhibit a lower speedup for larger cache sizes (e.g., the speedup of Q16 drops slightly when going from $C = 200$ to 300); however, the speedup for the whole workload exhibited a steady rise (2.18, 2.45 and 2.53 for $C = 100, 200$ and 300 respectively; figure omitted due to space reasons). Last, Fig. 11 depicts the results for the synthetic dataset.

7.3 Query Processing Speedup

Fig. 12 and 13 show the query processing time speedup for the AIDS/PDBS datasets. Interestingly, juxtaposing Fig. 12 against Fig. 7 (and Fig. 13 against Fig. 8) we see that reductions in the number of subgraph isomorphism tests do not directly translate into equal gains in query processing

Figure 9: Speedup in Number of Subgraph Isomorphism Tests for PDBS/Grapes(6) vs Zipf Skew α

Figure 10: Speedup in Number of Subgraph Isomorphism Tests for PPI/Grapes(6)/zipf - zipf($\alpha = 1.4$)/Query Groups

Figure 11: Speedup in Number of Subgraph Isomorphism Tests for Synthetic/Grapes(6)/zipf - zipf($\alpha = 2.4$)/Query Groups

Figure 12: Speedup in Query Processing Time for AIDS

Figure 13: Speedup in Query Processing Time for PDBS

times. This is due to some large graphs in the candidate sets not being pruned away by the current index contents. We would expect this to be ameliorated as cache sizes increase. Indeed Fig. 14 shows this for Grapes(6) as cache size varies from 500 to 1,000 and 1,500 queries. Results for other cases are similar and omitted for space reasons.

Fig. 15 shows the impact of Zipf skew α on query processing speedup for the Grapes(6) algorithms on the PDBS dataset. Again, with more skewness come greater benefits, up to impressive levels. Interestingly, juxtaposing Fig. 15 against Fig. 9 tells a different story. We see that reductions in the number of subgraph isomorphism tests translate into higher gains in query processing times. This is because of the replacement algorithm that maintains in the index those

Figure 14: Speedup in Query Processing Time for PDBS/Grapes(6) vs Cache Size

Figure 15: Speedup in Query Processing Time for PDBS/Grapes(6) vs Zipf Skew α

query graphs g with the higher utility; i.e., which help to avoid expensive subgraph isomorphism tests against graphs in the candidate sets. Fig. 16 and Fig. 17 show the speedup for the query processing time, corresponding to Fig. 10 and Fig. 11, respectively.

Last, Fig. 18 plots the index size for iGQ for $C = 500$ graph queries, versus that of the three algorithms we’ve considered so far, for the AIDS dataset. In the default configurations, iGQ adds a negligible space overhead on top of the base indexes (less than 1%). In addition to the default configurations for said algorithms, Fig. 18 also plots the index sizes for the immediately larger configurations (i.e., for max path length of 5 for Grapes and GGSX, and for trees of size 7, cycles of size 9, and 8192 bits per bitmap for CT-Index). Note that this minimal increase in the feature size results in almost double the space requirements for the base indexes. On the other hand, these larger indexes bring a performance improvement of less than 10% in all cases (figure omitted due to space reasons), which is virtually negligible when compared to the gains provided by iGQ .

Overall, iGQ is shown to introduce significant to impressive performance gains, against the state of the art methods in the literature. We have actually conducted a detailed performance evaluation of most related algorithms[21] and selected GGSX, Grapes(1), Grapes(6), and CT-Index as those showing the best performance. Regardless of the method, when incorporating iGQ with it, large performance gains ensue. These gains are robust and are manifested in all four different query workloads we have presented and, most importantly, with a minimal space overhead.

8. CONCLUSIONS

We have presented a novel perspective and solution to the graph querying problem, departing from related work in three ways: First, it constructs query indexes, as opposed to simply relying on dataset graph indexes. Second, it maintains the knowledge the system produced when executing previous queries. Third, it can be used to expedite both subgraph and supergraph queries. We showed how these can help improve the performance of future queries and provided formal proof of correctness. The proposed iGQ framework consists of (i) a subgraph index, (ii) a supergraph index, (iii) a method for efficiently maintaining the index,

Figure 16: Speedup in Query Processing Time for PPI/Grapes(6)/zipf - zipf($\alpha = 1.4$)/Query Groups

Figure 17: Speedup in Query Processing Time for Synthetic/Grapes(6)/zipf - zipf($\alpha = 2.4$)/Query Groups

Figure 18: Absolute Index Sizes (in MBytes) for AIDS

including a graph replacement policy, and (iv) any popular method for indexing and processing subgraph or supergraph queries. We incorporated iGQ within 3 popular methods from related work, showcasing its wide applicability. Last, our performance evaluation on both real-world and synthetic datasets with various query workloads showed iGQ ’s significant performance gains and negligible space overhead.

GSCALER: Synthetically Scaling A Given Graph

J.W. Zhang

Y.C. Tay
National University of Singapore
dcstayyc@nus.edu.sg

ABSTRACT

Enterprises and researchers often have datasets that can be represented as graphs (e.g. social networks). The owner of a large graph may want to scale it down to a smaller version, e.g. for application development. On the other hand, the owner of a small graph may want to scale it up to a larger version, e.g. to test system scalability. This paper investigates the *Graph Scaling Problem* (GSP):

Given a directed graph G and positive integers \tilde{n} and \tilde{m} , generate a similar directed graph \tilde{G} with \tilde{n} nodes and \tilde{m} edges.

This paper presents a graph scaling algorithm GSCALER for GSP. Analogous to DNA shotgun sequencing, GSCALER decomposes G into small pieces, scales them, then uses the scaled pieces to construct \tilde{G} . This construction is based on the indegree/outdegree correlation of nodes and edges.

Extensive tests with real graphs show that GSCALER is scalable and, for many graph properties, it generates a \tilde{G} that has greater similarity to G than other state-of-the-art solutions, like Stochastic Kronecker Graph and *UpSizeR*.

1. INTRODUCTION

The emergence of online social networks, like Facebook and Twitter, has attracted considerable research. However, their enormous sizes make any experiment on the entire graph impractical. It is therefore often necessary to obtain a smaller version of the graph for experiments. We call this the **scaling down** problem.

At the other end of the scale, a new social network service provider may have a small graph, but wants to test the scalability of their system. They may therefore want to have a larger (and necessarily) synthetic version of their current empirical graph. We call this the **scaling up** problem.

These two problems arise in other contexts as well, e.g. where the graph represents router topology or web links. They illustrate the *Graph Scaling Problem* (GSP):

Given a directed graph G and positive integers \tilde{n} and \tilde{m} , generate a similar directed graph \tilde{G} with \tilde{n} nodes and \tilde{m} edges.

There are many possible ways to define “similarity”, depending on the context, but we believe the definitions must all be in terms of graph properties, like indegree distribution, clustering coefficient, effective diameter, etc.

However, it is impossible for G and \tilde{G} to have exactly the same properties; e.g. if G and \tilde{G} have the same degree distributions, then the larger graph must necessarily have smaller density. One must therefore select the graph properties that are to be preserved when scaling. GSP facilitates this selection by allowing \tilde{n} and \tilde{m} to be specified separately.

Related work in the literature have objectives that are different from GSP. There are many papers on graph sampling, such as gSH, BFS, forest fire and frontier sampling [1, 3, 18, 21, 23, 30, 35]. They can be viewed as examples of scaling down, since they produce a \tilde{G} that is a subgraph of G ; this can have data protection issues that do not arise if \tilde{G} is synthetic. Moreover, graph sampling cannot generate a \tilde{G} that is larger than G .

Other related work use generative models that can produce a \tilde{G} that is smaller or larger than G . For example, an Erdős-Rényi model generates a graph of any size n with a specified edge probability p [9]; Chung and Lu’s model generates graphs with a specified degree distribution [4]; and Stochastic Kronecker Graphs [19, 20] are generated from an initiator by applying Kronecker product. However, these do not allow a choice of both \tilde{n} and \tilde{m} .

In contrast, we propose GSCALER, a solution to GSP that deviates from previous work by using a technique that is analogous to DNA shotgun sequencing [31]. The latter breaks a long DNA strand into smaller ones that are easier to sequence, then use these smaller sequences to reconstruct the sequence in the original strand.

Similarly, GSCALER (i) breaks the given G into two sets S_{in} and S_{out} of small pieces, (ii) scales them by size to \tilde{S}_{in} and \tilde{S}_{out} ; (iii) merges these pieces to give a set \tilde{S}_{bi} of larger pieces, then (iv) assembles \tilde{G} from the pieces in \tilde{S}_{bi} .

This paper makes the following contributions:

1. We present GSCALER, an algorithm for solving GSP.
2. We prove that GSCALER (i) does not generate multiple edges between two nodes, and (ii) has small degree distribution error even when the average degree of \tilde{G} differs from that of G .

3. We present experiments that compare GSCALER to 4 other techniques, using 2 real graphs and 7 properties.

We begin by surveying related work in Sec. 2. We describe GSCALER in Sec. 3, and prove that it does not generate multiple edges between any two nodes. Sec. 4 reviews the graph properties, state-of-the-art algorithms and datasets that are used for comparison. Sec. 5 then proves that GSCALER has small error, and presents the experimental comparison to other algorithms. We discuss the choice of \tilde{n} and \tilde{m} in Sec. 6, before Sec. 7 concludes with a summary.

2. RELATED WORK

The closest work in graph scaling from the literature are graph sampling algorithms and generative models.

For graph sampling, the main approaches are node-based sampling, edge-based sampling and traversal-based sampling which produce a subgraph of the original graph G .

Node-based sampling selects a set of nodes V_{sub} from G , then \tilde{G} is just the induced graph of this set of nodes V_{sub} . Authors in [32] pointed out that node-based sampling may not preserve a power law degree distribution because of bias induced by high degree nodes.

Similarly, traditional edge-based sampling selects edges randomly. However, this might result in a sparsely connected graph \tilde{G} [21]. Some other edge-based sampling variants [1, 16, 21] sample the graph using edge selection/deletion and combination with node selection/deletion.

Most graph sampling techniques focus on traversal-based sampling [14]. Breadth first sampling (BFS) [3, 18, 35] and random walk sampling (RW) [12, 30] are the most basic and well-known algorithms. Similar to BFS, snow ball sampling [13] (SBS) is widely used in sociology studies. Metropolis-Hastings Random Walk (MHRW) [12, 27] is a Markov-Chain Monte Carlo algorithm which samples unbiased subgraph in undirected social graphs. However, MHRW suffers from *sample-rejection problem*. Later, rejection-controlled Metropolis-Hastings (RCMH) [26] is proposed to reduce the sample-rejection ratio.

Frontier sampling is a multi-dimensional random walk which results in better estimators for some graph properties [30]. A probabilistic version of SBS, forest fire (FF) [21, 23] captures some important observations in real social networks, e.g. small diameter.

Most traversal-based sampling requires random access to a node's neighbors, which might not be feasible for large graphs (that cannot fit into memory). Hence, streaming graph sampling algorithms are proposed, e.g. induced edge sampling (ES-i) [2]. As mentioned previously, graph sampling algorithms are limited to *scaling down* problem.

For generative models, the Erdős-Rényi model generates a graph of any size n with a specified edge probability p [9]. There are variants of random models that generate graphs with specific graph properties [4, 28], e.g. the Chung-Lu model generates graphs with a specified degree distribution.

One group of generative models [5, 6, 11, 17] employ the strategy of *preferential attachment*. They obey a simple rule: a new node u attaches to the graph at each time step, and adds an edge e_{uv} to an existing node v with a probability p proportional to the degree of the node v .

Another type of generative models is *recursive matrix* model [7, 19, 20], which recursively multiplies the adjacency matrix. For example, Stochastic Kronecker Graph (SKG) [20]

Notation	Description
$G(V, E)$	original graph
$\tilde{G}(\tilde{V}, \tilde{E})$	scaled graph
n/\tilde{n}	number of nodes in G/\tilde{G}
m/\tilde{m}	number of edges in G/\tilde{G}
f_{in}/\tilde{f}_{in}	G/\tilde{G} 's indegree distribution
f_{out}/\tilde{f}_{out}	G/\tilde{G} graph's outdegree distribution
f_{bi}/\tilde{f}_{bi}	G/\tilde{G} graph's bidegree distribution
$f_{corr}/\tilde{f}_{corr}$	G/\tilde{G} graph's edge correlation distribution
S_{in}/\tilde{S}_{in}	set of pieces with incoming edges in G/\tilde{G}
S_{out}/\tilde{S}_{out}	set of pieces with outgoing edges in G/\tilde{G}
\tilde{S}_{bi}	set of pieces with incoming and outgoing edges in \tilde{G}
ct_{Δ}	count function of the pieces in set Δ , Δ can be S_{in}, \tilde{S}_{in} and so on.
$I(\alpha')/O(\alpha')$	total number of available incoming/outgoing edges for nodes with bidegree α'
$D(f, \tilde{f})$	KS-D statistics of between f and \tilde{f}

Table 1: Notation

recursively multiplies the graph initiator K_1 through Kronecker product, which results in a self-similar graph. SKG captures most social network properties, such as small diameter and power law degree distribution.

Scaling problem appears in other fields as well. For example, *UpSizeR* is a pioneer tool which synthetically scales a relational dataset [33]. *UpSizeR*'s focus is on preserving correlation among tuples from multiple tables. In relational terms, *GSP* requires preservation of correlation among tuples in a single table (for the edges).

For Resource Description Framework (RDF), the AO benchmark [8] is the first tool that scales down an RDF dataset. Later, RBench [29] is proposed to both scale down and up. However, these two benchmarks are evaluated with different metrics (*dataset coherence*, *relationship specialty*, *literal diversity*), so it would be unfair to use them for comparison.

3. GRAPH SCALER (GSCALER)

Given a graph $G(V, E)$, $|V|$ and $|E|$ may need to scale by different factors to maintain similarity for certain properties (e.g. density). Hence, GSCALER allows the user to specify the target \tilde{n} and \tilde{m} . As shown in Fig.1, the scaling has the following 4 steps:

Figure 1: The 4 steps in Gscaler.

GSCALER first decomposes G into 2 sets S_{in} and S_{out} . S_{in} consists of **pieces**, where a piece is a node with its incoming edges (minus the source nodes). Similarly, S_{out} consists of

Algorithm 1: GSCALER(G, \tilde{n}, \tilde{m})

```
1  $\widetilde{S_{in}}, \widetilde{S_{out}}, f_{bi}, f_{corr} = \text{DECOMPOSE}(G)$ 
2  $\widetilde{S_{in}} = \text{SCALING}(\widetilde{S_{in}}, \tilde{n}, \tilde{m})$ 
3  $\widetilde{S_{out}} = \text{SCALING}(\widetilde{S_{out}}, \tilde{n}, \tilde{m})$ 
4  $\widetilde{S_{bi}} = \text{NODE\_SYNTHESIS}(\widetilde{S_{in}}, \widetilde{S_{out}}, f_{bi})$ 
5  $\widetilde{G} = \text{EDGE\_SYNTHESIS}(\widetilde{S_{bi}}, f_{corr})$ 
```

pieces, where a piece is a node with its outgoing edges (minus the target nodes). Each node in G generates 2 pieces, one in $\widetilde{S_{in}}$ and one in $\widetilde{S_{out}}$.

After that, GSCALER scales $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$ to get the scaled sets of pieces $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$ with \tilde{n} nodes and \tilde{m} edges.

In node synthesis, $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$ are used to form a set $\widetilde{S_{bi}}$ of larger pieces. Each new piece has a node with incoming edges (with no source nodes) and outgoing edges (with no target nodes); it will generate one node in \widetilde{G} .

The last step (edge synthesis) is to link pieces in $\widetilde{S_{bi}}$ which finally results in \widetilde{G} . Edge synthesis is similar to a jigsaw puzzle, where you want to fit the small pieces together. Algo. 1 summaries the workflow for GSCALER.

In the following, we will explain each step in detail, and use a running example to show how G is scaled to \widetilde{G} in Fig.1. As presented in Fig.1, $n = 3, \tilde{n} = 6, m = 3, \tilde{m} = 7$.

3.1 DECOMPOSE

This step is straightforward, and Fig. 1 shows the pieces in $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$ from decomposing G .

3.2 SCALING

To simplify the explanation, we just use $\widetilde{S_{in}}$ for demonstration. Let $N = \{0, 1, 2, 3, \dots\}$. We use the *count* function ct to denote k pieces in Δ has property x :

$$ct_{\Delta}(x) = k, k \in N \quad (1)$$

For example, $ct_{\widetilde{S_{in}}}(x) = k$ means k pieces in $\widetilde{S_{in}}$ have indegree x . For both $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$, the scaling process takes the following three steps:

- **node scaling.** For indegree x , let $A_x = ct_{\widetilde{S_{in}}}(x) \times \frac{\tilde{n}}{n}$. As A_x might not be an integer, we round-off $\widetilde{S_{in}}$ as follows:

$$ct_{\widetilde{S_{in}}}(x) = \begin{cases} \lfloor A_x \rfloor & \text{with probability } A_x - \lfloor A_x \rfloor \\ \lceil A_x \rceil & \text{with probability } \lceil A_x \rceil - A_x \end{cases} \quad (2)$$

For example, if $A_x = 4.8$, then with 0.8 probability, $ct_{\widetilde{S_{in}}}(x) = 5$, and with 0.2 probability, $ct_{\widetilde{S_{in}}}(x) = 4$. Hence, Eq.2 can be rewritten as

$$E[ct_{\widetilde{S_{in}}}(x)] = ct_{\widetilde{S_{in}}}(x) \times \frac{\tilde{n}}{n} \quad (3)$$

Fig.2 shows the $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$ that we get after this scaling.

- **node adjustment.** With randomness in node scaling (Eq.2), we may have $|\widetilde{S_{in}}| \neq \tilde{n}$. If so, $|\tilde{n} - |\widetilde{S_{in}}||$ nodes

Figure 2: $\widetilde{S_{in}}, \widetilde{S_{out}}$ after node scaling for G in Fig.1.

Algorithm 2: SCALING($\widetilde{S_{in}}, \tilde{n}, \tilde{m}$)

```
1 node_scaling( $\widetilde{S_{in}}, \tilde{n}$ )
2 node_adjustment( $\widetilde{S_{in}}, \tilde{n}, \widetilde{S_{in}}$ )
  /*  $h_0/l_0$  is the upper/lower bound where  $x$ 
   varies. By default,  $h_0/l_0$  should be the
   highest/lowest degree in the graph.  $h_0/l_0$ 
   will be further extended if needed.  $t$  is the
   edge difference threshold where the loop
   stops.  $ct(x)$  refers to  $ct_{\widetilde{S_{in}}}(x)$ . */
3 initialize  $h = h_0, l = l_0, t$ 
5 while  $|\sum_x ct(x) \times x - \tilde{m}| > t$  do
6   if  $l \geq h$  then
7      $l = l_0; h = h_0;$ 
8   if  $\tilde{m} > \sum_x ct(x) \times x$  then
9     if  $ct(l) > 0$  then
10        $ct(l) - -; ct(h) + +;$ 
11        $l + +; h - -;$ 
12     else  $l + +;$ 
13   else
14     if  $ct(h) > 0$  then
15        $ct(l) + +; ct(h) - -;$ 
16        $l + +; h - -;$ 
17     else  $h - -;$ 
18 adjust  $|\sum_x ct(x) \times x - \tilde{m}|$  edges
```

with random degree are added to or removed from $\widetilde{S_{in}}$. For G in Fig. 1, such adjustment is not needed.

- **edge adjustment.** Next, the number of scaled edges must equal to \tilde{m} , i.e. $\sum_x ct_{\widetilde{S_{in}}}(x) \times x = \tilde{m}$.

If $\sum_x ct_{\widetilde{S_{in}}}(x) \times x < \tilde{m}$, we increase the number of high degree nodes, and decrease the number of low degree nodes. If $\sum_x ct_{\widetilde{S_{in}}}(x) \times x > \tilde{m}$, we decrease the number of high degree nodes, and increase the number of low degree nodes. The details are shown in Algo. 2.

In our running example, $\sum_x ct_{\widetilde{S_{in}}}(x) \times x = 6 < 7 = \tilde{m}$. Hence, we increase the number of high degree nodes (indegree=2), and decrease the number of low degree (indegree=1) nodes. Thus, we have 1 node with indegree=2 and 5 nodes with indegree=1 for $\widetilde{S_{in}}$. After the edge adjustment, the correct $\widetilde{S_{in}}, \widetilde{S_{out}}$ are shown in Fig. 1.

3.3 NODE SYNTHESIS

Now we have $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$, and we match 1 piece in $\widetilde{S_{in}}$ to 1 piece in $\widetilde{S_{out}}$ and merge them to give a larger piece. This synthesis follows a *bidegree* distribution $f_{bi} : N^2 \rightarrow [0, 1]$, where $f_{bi}(d_1, d_2) = z$ means a fraction z of nodes have bidegree (d_1, d_2) . We say a node u has bidegree (d_1, d_2) if it has indegree= d_1 and outdegree= d_2 . For G in Fig. 1, the corresponding f_{bi} is listed in Table 2.

GSCALER loops through $f_{bi}(d_1, d_2)$ to synthesize nodes. However, for a desired bidegree (d_1, d_2) , $\widetilde{S_{in}}$ and $\widetilde{S_{out}}$ may not have the necessary pieces. Hence, a *neighboring* (d_1', d_2') will be used. GSCALER uses a greedy heuristic that matches pieces by minimizing the Manhattan distance

$$|(d_1, d_2) - (d_1', d_2')|_1 = |d_1 - d_1'| + |d_2 - d_2'|.$$

Algorithm 3: NODE SYNTHESIS ($\widetilde{S}_{in}, \widetilde{S}_{out}, f_{bi}$)

```

1 while  $\widetilde{S}_{in}$  and  $\widetilde{S}_{out}$  not empty do
2   for  $f_{bi}(d_1, d_2)$  do
3     while  $[f_{bi}(d_1, d_2) \times \widetilde{m}] > 0$  do
4        $(d_1', d_2') \leftarrow \text{Manhattan}(d_1, d_2)$ 
5        $\widetilde{S}_{bi} \leftarrow (d_1', d_2')$ 
6       update  $\widetilde{S}_{in}, \widetilde{S}_{out}, f_{bi}(d_1, d_2)$ 

```

For Table 2, when GSCALER sees $f_{bi}(1, 0) = \frac{1}{3}$, it will first generate 1 node with bidegree (1, 0), and generate the other node with bidegree (1, 1). Next, GSCALER sees $f_{bi}(1, 1) = \frac{1}{3}$, two nodes both having bidegree (1, 1) are generated. Lastly, GSCALER sees $f_{bi}(1, 2) = \frac{1}{3}$, and two nodes with bidegree (1, 2), and (2, 2) are generated.

Algo.3 summarizes the node synthesis. The synthesized pieces for \widetilde{S}_{bi} in \widetilde{G} are shown in Fig. 1. Note that each piece in \widetilde{S}_{bi} maps to a node in \widetilde{G} .

3.4 EDGE SYNTHESIS

Now we are almost done with the graph scaling, we only need to link the edges. This is similar to a jigsaw puzzle, we only need to make sure that each piece links to another correctly. When linking the pieces from \widetilde{S}_{bi} , we link 1 outgoing edge from a source node $v_s \in \widetilde{S}_{bi}$ to 1 incoming edge from a target node $v_t \in \widetilde{S}_{bi}$. There are numerous ways of joining the nodes. GSCALER synthesizes edges based on the edge correlation function

$$f_{corr} : N^2 \times N^2 \rightarrow [0, 1],$$

where $f_{corr}(\alpha_s, \alpha_t) = z$ means a fraction z of the edges have a source node with bidegree α_s and a target node with bidegree α_t . The f_{corr} for G is listed in Table 3.

Instead of synthesizing edges one by one based on f_{corr} directly, GSCALER undergoes *Correlation Function Scaling* to scale f_{corr} to \widetilde{f}_{corr} for \widetilde{G} . After a suitable \widetilde{f}_{corr} is found, GSCALER links edges based on \widetilde{f}_{corr} .

3.4.1 Correlation Function Scaling

GSCALER loops through f_{corr} to produce \widetilde{f}_{corr} . For each $f_{corr}(\alpha_s, \alpha_t)$, it does the following *Iterative Correlating*:

Manhattan Minimization

GSCALER chooses the *closest* (α_s', α_t') for \widetilde{f}_{corr} by minimizing $\|\alpha_s - \alpha_s'\|_1 + \|\alpha_t - \alpha_t'\|_1$. For $f_{corr}((1, 2), (1, 0)) = 1/3$ in Table 3, GSCALER chooses (1, 2) for α_s' and (1, 0) for α_t' .

Increment Probability Maximization

GSCALER increments $\widetilde{f}_{corr}(\alpha_s', \alpha_t')$ by p , where p needs to be the **largest** number that satisfies the following constraints:

- C1.** $p \leq f_{corr}(\alpha_s, \alpha_t)$.
- C2.** $p \leq \min\{\frac{O(\alpha_s')}{\widetilde{m}}, \frac{I(\alpha_t')}{\widetilde{m}}\}$, where $I(\alpha_t')$ is the total number of available *incoming* edges for nodes with bidegree α_t' , and $O(\alpha_s')$ is the total number of available *outgoing* edges for nodes with bidegree α_s' . C2 guarantees incremented number of edges does not exceed the total available number of edges of source nodes and target nodes.
- C3.** $p \leq \frac{ct_{\widetilde{S}_{bi}}(\alpha_s') \times ct_{\widetilde{S}_{bi}}(\alpha_t')}{\widetilde{m}} - \widetilde{f}_{corr}(\alpha_s', \alpha_t')$. C3 ensures

$f_{bi}(1, 0) = \frac{1}{3}$
$f_{bi}(1, 1) = \frac{1}{3}$
$f_{bi}(1, 2) = \frac{1}{3}$

Table 2: Bidegree distribution for G in Fig. 1.

$f_{corr}((1, 2), (1, 0)) = \frac{1}{3}$
$f_{corr}((1, 2), (1, 1)) = \frac{1}{3}$
$f_{corr}((1, 1), (1, 2)) = \frac{1}{3}$

Table 3: Edge Correlation for G in Fig.1.

the total number of edges from source nodes to target nodes is not more than the maximal number of edges allowed from source nodes to target nodes (*no multiple edges*).

For $f_{corr}((1, 2), (1, 0)) = 1/3$ in Table 3:

By **C1**, $p \leq 1/3$.

By **C2**, $p \leq \min\{\frac{O((1, 2))}{7}, \frac{I((1, 0))}{7}\} = \min\{\frac{2}{7}, \frac{1}{7}\} = \frac{1}{7}$.

By **C3**, $p \leq \frac{ct_{\widetilde{S}_{bi}}((1, 2)) \times ct_{\widetilde{S}_{bi}}((1, 0))}{7} - \widetilde{f}_{corr}((1, 2), (1, 0)) = \frac{1 \times 1}{7} - 0$.

Hence, the incremental value is $p = \min\{\frac{1}{3}, \frac{1}{7}, \frac{1}{7}\} = \frac{1}{7}$.

Value Update

Next, GSCALER updates the distributions:

- $\widetilde{f}_{corr}(\alpha_s', \alpha_t') \leftarrow \widetilde{f}_{corr}(\alpha_s', \alpha_t') + p$.
- $O(\alpha_s') \leftarrow O(\alpha_s') - p \times \widetilde{m}$.
- $I(\alpha_t') \leftarrow I(\alpha_t') - p \times \widetilde{m}$.

For $f_{corr}((1, 2), (1, 0)) = 1/3$ in Table 3, GSCALER gets

$\widetilde{f}_{corr}((1, 2), (1, 0)) = 1/7$, $O((1, 2)) = 1$, $I((1, 0)) = 0$. Table 4 shows the resulting scaled \widetilde{f}_{corr} .

After iterative correlating, and due to the no multiple edges constraint, it is possible that $\sum \widetilde{f}_{corr}(\alpha_s', \alpha_t') < 1$, which we fix by **random swapping**. This swap first randomly permutes the leftover bidegree from I and O without violating C3, then takes one element with bidegree γ_s' from O and one element with bidegree γ_t' from I to swap with generated $\widetilde{f}_{corr}(\alpha_s', \alpha_t')$.

The idea is to break 1 edge from some source node v_s with bidegree α_s' to some target node v_t with bidegree α_t' , and form 2 new edges: 1 edge pointing from some node with bidegree γ_s' to the other node with bidegree α_t' , and 1 edge pointing from some node with bidegree α_s' to some node with bidegree γ_t' . If C3 allows, then update \widetilde{f}_{corr} as follows:

- $\widetilde{f}_{corr}(\alpha_s', \gamma_t') \leftarrow \widetilde{f}_{corr}(\alpha_s', \gamma_t') + \frac{1}{\widetilde{m}}$.
- $\widetilde{f}_{corr}(\gamma_s', \alpha_t') \leftarrow \widetilde{f}_{corr}(\gamma_s', \alpha_t') + \frac{1}{\widetilde{m}}$.
- $\widetilde{f}_{corr}(\alpha_s', \alpha_t') \leftarrow \widetilde{f}_{corr}(\alpha_s', \alpha_t') - \frac{1}{\widetilde{m}}$.

One successful swap thus increases \widetilde{f}_{corr} by $\frac{1}{\widetilde{m}}$.

In the worst case (this did not happen in our experiments), after random swaps, $\sum \widetilde{f}_{corr}(\alpha_s', \alpha_t') < 1$ might still hold. We just leave \widetilde{f}_{corr} as it is, and we will introduce some *dummy nodes* to link these $(1 - \sum \widetilde{f}_{corr}(\alpha_s', \alpha_t')) \times \widetilde{m}$ edges

$\widetilde{f}_{corr}((1, 2), (1, 0)) = \frac{1}{7}$	$\widetilde{f}_{corr}((1, 2), (1, 1)) = \frac{1}{7}$
$\widetilde{f}_{corr}((1, 1), (1, 2)) = \frac{1}{7}$	$\widetilde{f}_{corr}((2, 2), (1, 1)) = \frac{2}{7}$
$\widetilde{f}_{corr}((1, 1), (2, 2)) = \frac{2}{7}$	

Table 4: Edge Correlation for \widetilde{G} in Fig. 1.

Figure 3: Local linking of source and destination.

later in Sec.3.4.2.

3.4.2 Edge Linking

After \widetilde{f}_{corr} is generated, GSCALER links the $p \times \widetilde{m}$ edges locally for each $\widetilde{f}_{corr}(\alpha_s', \alpha_t') = p$. Note that some **linking** steps are related, since α_s' might appear in a series of local linking steps, such as

$$\widetilde{f}_{corr}(\alpha_s', \alpha_{t_1}') = p_1, \dots, \widetilde{f}_{corr}(\alpha_s', \alpha_{t_k}') = p_k$$

Hence, one must make sure that after $\widetilde{f}_{corr}(\alpha_s', \alpha_{t_1}') = p_1$ is done, $\widetilde{f}_{corr}(\alpha_s', \alpha_{t_2}') = p_2, \dots, \widetilde{f}_{corr}(\alpha_s', \alpha_{t_k}') = p_k$ are still possible to be linked with no multiple edges. To emphasize the importance of this step, we use the following example to demonstrate both good and bad approaches.

In Fig.3, \widetilde{S}_{bi} and \widetilde{f}_{corr} are presented at the top. \widetilde{S}_{bi} has 2 pieces of bidegree (2,2), 2 pieces of bidegree (1,0), and 2 pieces of bidegree (0,1). The dotted edges represent newly linked edges at each step. If an edge has no source or target node attached, then it has not linked any two nodes yet. Example A demonstrates a failed strategy, while example B demonstrates a successful strategy.

For $\widetilde{f}_{corr}((0,1), (2,2)) = \frac{1}{3}$, it corresponds to local linking step ①, which links two edges from (0,1) to (2,2). Both examples link edges successfully. Example A links all 2 edges to 1 target node with bidegree (2,2), whereas example B links 2 edges to 2 different target nodes with bidegree (2,2).

For $\widetilde{f}_{corr}((2,2), (1,0)) = \frac{1}{3}$, it corresponds to local linking step ②, which links 2 edges from (2,2) to (1,0). Both examples link edges successfully. Example A links all 2 edges from 1 source node with bidegree (2,2). Example B links 2 edges from 2 different source nodes with bidegree (2,2).

For $\widetilde{f}_{corr}((2,2), (2,2)) = \frac{1}{3}$, it corresponds to local linking step ③, which links edges from (2,2) to (2,2). Example A produces multiple edges, which is not allowed, whereas example B successfully produces the graph.

Apart from the multiple edge constraint, the algorithm must be efficient as well. The naive idea of back tracking previous edge linking processes is obviously not practical for large graphs. GSCALER not only generates \widetilde{G} with no multiple edges, it also links edges in **linear** time (see below). GSCALER first selects the proper *source* nodes L_s and *target* nodes L_t , and then link the edges from L_s to L_t .

Let $\mathcal{S}_{\alpha_s'}/\mathcal{T}_{\alpha_t'}$ be a *queue* of the source/target nodes with *bidegree* α_s'/α_t' from \widetilde{S}_{bi} . For each $\widetilde{f}_{corr}(\alpha_s', \alpha_t') = p$, GSCALER dequeue&enqueue $p \times \widetilde{m}$ elements from $\mathcal{S}_{\alpha_s'}$ to L_s , and dequeue&enqueue $p \times \widetilde{m}$ elements from $\mathcal{T}_{\alpha_t'}$ to L_t . More specifically, whenever one element is dequeued from

$\mathcal{S}_{\alpha_s'}/\mathcal{T}_{\alpha_t'}$, it will be put into L_s/L_t , and then been enqueued to $\mathcal{S}_{\alpha_s'}/\mathcal{T}_{\alpha_t'}$ again. For example, if we dequeue&enqueue 7 elements from $\mathcal{S}_{(1,1)} = [1, 2, 3, 4, 5]$ to L_s , then $L_s = [1, 2, 3, 4, 5, 1, 2]$, and $\mathcal{S}_{(1,1)} = [3, 4, 5, 1, 2]$. In general,

$$L_s = \{u_1^{\lceil \frac{p \times \widetilde{m}}{|\mathcal{S}_{\alpha_s'}|} \rceil}, \dots, u_{r_s}^{\lceil \frac{p \times \widetilde{m}}{|\mathcal{S}_{\alpha_s'}|} \rceil}, u_{r_s+1}^{\lfloor \frac{p \times \widetilde{m}}{|\mathcal{S}_{\alpha_s'}|} \rfloor}, \dots, u_{|\mathcal{S}_{\alpha_s'}|}^{\lfloor \frac{p \times \widetilde{m}}{|\mathcal{S}_{\alpha_s'}|} \rfloor}\}, \forall u_i \in \mathcal{S}_{\alpha_s'}$$

$$L_t = \{v_1^{\lceil \frac{p \times \widetilde{m}}{|\mathcal{T}_{\alpha_t'}|} \rceil}, \dots, v_{r_t}^{\lceil \frac{p \times \widetilde{m}}{|\mathcal{T}_{\alpha_t'}|} \rceil}, v_{r_t+1}^{\lfloor \frac{p \times \widetilde{m}}{|\mathcal{T}_{\alpha_t'}|} \rfloor}, \dots, v_{|\mathcal{T}_{\alpha_t'}|}^{\lfloor \frac{p \times \widetilde{m}}{|\mathcal{T}_{\alpha_t'}|} \rfloor}\}, \forall v_j \in \mathcal{T}_{\alpha_t'}$$

$$r_s = p \times \widetilde{m} \mod |\mathcal{S}_{\alpha_s'}|, \quad r_t = p \times \widetilde{m} \mod |\mathcal{T}_{\alpha_t'}|, \quad (4)$$

where v_1^k means v_1 appears k times in L_t , and k is called the **multiplicity** of v_1 .

After L_s and L_t are generated, GSCALER links edges from L_s to L_t . Before that, we prove a theorem for **Compound Multiplicity Reduction**; we later use this to show GSCALER does not generate multiple edges between two nodes.

THEOREM 1. [Compound Multiplicity Reduction]. *Given multisets $\mathbb{U} = \{u_1^{m_{u_1}}, \dots, u_{\theta_0}^{m_{u_{\theta_0}}}\}$, $\mathbb{V} = \{v_1^{m_{v_1}}, \dots, v_{\theta_1}^{m_{v_{\theta_1}}}\}$,*

$$\sum_{u_i \in \mathbb{U}} m_{u_i} = |\mathbb{U}| = |\mathbb{V}| = \sum_{v_j \in \mathbb{V}} m_{v_j}, \quad (5)$$

$$\max_{u_i \in \mathbb{U}} m_{u_i} - \min_{u_i \in \mathbb{U}} m_{u_i} \leq 1, \quad (6)$$

$$\text{and } \max_{v_j \in \mathbb{V}} m_{v_j} - \min_{v_j \in \mathbb{V}} m_{v_j} \leq 1, \quad (7)$$

there exists a multiset $\mathbb{W} = \{w_k | w_k(0) \in \mathbb{U}, w_k(1) \in \mathbb{V}\}$

$$\text{such that } \mathbb{U} = \bigcup_k \{w_k(0)\}, \quad \mathbb{V} = \bigcup_k \{w_k(1)\}, \quad (8)$$

$$\max_{w_k \in \mathbb{W}} m_{w_k} - \min_{w_k \in \mathbb{W}} m_{w_k} \leq 1, \quad (9)$$

$$\forall w_k \in \mathbb{W}, m_{w_k} \leq \lceil \frac{|\mathbb{W}|}{\theta_0 \times \theta_1} \rceil. \quad (10)$$

PROOF. Reorder \mathbb{U}, \mathbb{V} to

$$\mathbb{U} = (u_1, \dots, u_1, u_2, \dots, u_2, \dots, u_{\theta_0}, \dots, u_{\theta_0}),$$

$$\mathbb{V} = (v_1, v_2, \dots, v_{\theta_1}, v_1, v_2, \dots, v_{\theta_1}, v_1, \dots).$$

Construct \mathbb{W} as follows: $\forall w_k \in \mathbb{W}$, $w_k = (\mathbb{U}(k), \mathbb{V}(k))$, where $\mathbb{U}(k)$ means the k th element in \mathbb{U} . Therefore, Eq.8 is satisfied. Further, for any u_i , let

$$\mathbb{W}_{u_i} = ((u_i, \mathbb{V}(c_i)), (u_i, \mathbb{V}(c_i + 1)), \dots, (u_i, \mathbb{V}(d_i)))$$

be the sequence of all elements in \mathbb{W} containing u_i as first coordinate. Consider $\mathbb{V}_{u_i} = (\mathbb{V}(c_i), \mathbb{V}(c_i + 1), \dots, \mathbb{V}(d_i))$, a sequence of elements in \mathbb{V} pairing with u_i . Note \mathbb{V}_{u_i} is a *periodic sequence* with *period* $= \theta_1$. Thus, the maximum multiplicity in \mathbb{V}_{u_i} is $\lceil \frac{|\mathbb{V}_{u_i}|}{\theta_1} \rceil$, and similarly for \mathbb{W}_{u_i} . Hence, the maximum multiplicity of \mathbb{W} is

$$\max_{w_k \in \mathbb{W}} m_{w_k} = \max_{1 \leq i \leq \theta_0} \lceil \frac{|\mathbb{W}_{u_i}|}{\theta_1} \rceil \quad (11)$$

It is trivial that

$$|\mathbb{V}_{u_i}| = m_{u_i}, \forall i, 1 \leq i \leq \theta_0 \quad (12)$$

Moreover, by Eq.6, we will have

$$\forall u_i \in \mathbb{U}, m_{u_i} \leq \lceil \frac{|\mathbb{U}|}{\theta_0} \rceil \quad (13)$$

Hence, by Eq.11, Eq.12, Eq.13, we will have

$$\max_{w_k \in \mathbb{W}} m_{w_k} = \max_{1 \leq i \leq \theta_0} \lceil \frac{|\mathbb{V}_{u_i}|}{\theta_1} \rceil \leq \lceil \frac{|\mathbb{U}|}{\theta_0} \rceil = \lceil \frac{|\mathbb{U}|}{\theta_0 \times \theta_1} \rceil \quad (14)$$

Since $|\mathbb{U}| = |\mathbb{W}|$, therefore

$$\max_{w_k \in \mathbb{W}} m_{w_k} \leq \lceil \frac{|\mathbb{W}|}{\theta_0 \times \theta_1} \rceil, \quad (15)$$

so Eq.10 holds. Similarly, the minimum multiplicity of \mathbb{W} is

$$\min_{w_k \in \mathbb{W}} m_{w_k} = \min_{1 \leq i \leq \theta_0} \lfloor \frac{|\mathbb{V}_{u_i}|}{\theta_1} \rfloor \geq \lfloor \frac{|\mathbb{W}|}{\theta_0 \times \theta_1} \rfloor \quad (16)$$

Eq.9 follows from Eq.15 and Eq.16. We call such a \mathbb{W} a **compound multiset**. \square

For edge linking between L_s and L_t , GSCALER links $u_1 \in L_s$ to $v_2 \in L_t$ to form one edge (u_1, v_2) in L_e (edge set). By Eq.4, L_s/L_t satisfies \mathbb{U}/\mathbb{V} in *Theorem 1* respectively, and it is easy to see that L_e is the compound \mathbb{W} in *Theorem 1*.

THEOREM 2. *Given non-empty $L_s(\mathbb{U})$ dequeued&enqueued from $\mathcal{S}_{\alpha_s'}$, and non-empty $L_t(\mathbb{V})$ dequeued&enqueued from $\mathcal{T}_{\alpha_t'}$, the maximum multiplicity for edge set $L_e(\mathbb{W})$ as described in *Theorem 1* is 1.*

PROOF. If $|L_s| \leq |\mathcal{S}_{\alpha_s'}|$, then every element in L_s is unique. Hence, the maximum multiplicity for elements in L_s is 1, so L_e has maximum multiplicity of 1. The case is similar for $|L_t| \leq |\mathcal{T}_{\alpha_t'}|$.

If $|L_s| > |\mathcal{S}_{\alpha_s'}|$ and $|L_t| > |\mathcal{T}_{\alpha_t'}|$, then L_s has $|\mathcal{T}_{\alpha_s'}|$ distinct elements, and L_t has $|\mathcal{T}_{\alpha_t'}|$ distinct elements. By *Theorem 1*, the maximum multiplicity of elements in L_e is

$$\lceil \frac{|L_e|}{|\mathcal{S}_{\alpha_s'}| \times |\mathcal{T}_{\alpha_t'}|} \rceil \quad (17)$$

Since $|L_s| = |L_e|$, and L_s has $\widetilde{f_{corr}}(\alpha_s', \alpha_t') \times \tilde{m}$ elements, the maximum multiplicity of elements in L_e is

$$\lceil \frac{\widetilde{f_{corr}}(\alpha_s', \alpha_t') \times \tilde{m}}{|\mathcal{S}_{\alpha_s'}| \times |\mathcal{T}_{\alpha_t'}|} \rceil$$

Moreover, by C3 in Sec.3.4.1, we know that

$$\widetilde{f_{corr}}(\alpha_s', \alpha_t') \times \tilde{m} \leq |\mathcal{S}_{\alpha_s'}| \times |\mathcal{T}_{\alpha_t'}|, \quad (18)$$

$$\text{so } \lceil \frac{|L_e|}{|\mathcal{S}_{\alpha_s'}| \times |\mathcal{T}_{\alpha_t'}|} \rceil = \lceil \frac{\widetilde{f_{corr}}(\alpha_s', \alpha_t') \times \tilde{m}}{|\mathcal{S}_{\alpha_s'}| \times |\mathcal{T}_{\alpha_t'}|} \rceil \leq 1 \quad (19)$$

\square

Hence, by *Theorem 2*, there are no multiple edges from L_s to L_t . Therefore, GSCALER successfully produces a graph without multiple edges.

Moreover, the generation runs in **linear** time: For each $\widetilde{f_{corr}}(\alpha_s', \alpha_t')$, the generation for L_s and L_t is in linear time: After L_s, L_t are generated, the L_e is formed by sequentially matching the elements in L_s and L_t as described in *Theorem 1*. Hence, the total edge linking time is *linear*. Given the edge correlation $\widetilde{f_{corr}}$ in Table 4, GSCALER generates \tilde{G} as presented in Fig. 1.

Finally, as stated at the end of Sec.3.4.1, there might be some small possibility that $\sum \widetilde{f_{corr}}(\alpha_s', \alpha_t') < 1$ holds. This is the theoretical worst case (which has not happened in our experiments). To resolve this, GSCALER introduces ϵ *dummy nodes* into \tilde{G} for the purpose of maintaining degree distribution similarity. After the dummy nodes are introduced, all the $1 - \sum \widetilde{f_{corr}}(\alpha_s', \alpha_t')$ edges are linked to

Algorithm 4: EDGE SYNTHESIS($\widetilde{S}_{bi}, f_{corr}$)

```

1  $\widetilde{f_{corr}} \leftarrow \text{correlation\_function\_scaling}(\widetilde{S}_{bi}, f_{corr})$ 
2 while  $\widetilde{f_{corr}}(\alpha_s', \alpha_t') = p$  do
   /* produce the  $L_s$  and  $L_t$  */
3    $L_s, L_t \leftarrow \text{local\_set}(\alpha_s', \alpha_t', p, \tilde{m})$ 
   /* link the edges from  $L_s$  to  $L_t$  */
4    $\tilde{G} \leftarrow \text{edge\_linking}(L_s, L_t)$ 
5 add dummy nodes to  $\tilde{G}$  (if necessary)
```

these dummy nodes. To avoid multiple edges, we can set $\epsilon = \max_{\alpha} \{I(\alpha), O(\alpha)\}$; this ϵ is obviously not the smallest possible. However, such an ϵ is already small(negligible) compared to $|\tilde{G}|$, and such a scenario is rare. Algo.4 summarizes the edge synthesis.

4. EVALUATION

We first review the graph properties that we use for similarity measurement.

4.1 Graph Properties

There are numerous graph properties that can be chosen as the similarity measurement criteria, e.g. degree distribution, diameter, k-core distribution, etc. We choose the 7 most common graph properties used in the literature. Let $N = \{0, 1, 2, 3, \dots\}$ and consider the following local and global graph properties:

1. **Indegree distribution** $f_{in} : N \rightarrow [0, 1]$
 $f_{in}(d) = z$ means a portion z of nodes have indegree d .
2. **Outdegree distribution** $f_{out} : N \rightarrow [0, 1]$
 $f_{out}(d) = z$ means a portion z of nodes have outdegree d .
3. **Bidegree distribution** $f_{bi} : N^2 \rightarrow [0, 1]$
 Defined in Sec 3.3.
4. **Ratio of largest strongly connected component (SCC)**
 An SCC of G is a maximal set of nodes such that for every node pair u and v , there is a directed path from u to v and another from v to u . The ratio is the number of nodes in the SCC divided by $|V|$.

5. **Average clustering coefficient (CC)**
 For node v_i , let N_i be the set of its neighbors. The local clustering coefficient [34] C_i for nodes v_i is defined by

$$C_i = \frac{|\{(v_j, v_k) : v_j, v_k \in N_i, (v_j, v_k) \in E\}|}{|N_i|(|N_i| - 1)}$$

The average clustering coefficient [15] $\bar{C} = \frac{\sum_{v_i \in V} C_i}{|V|}$

6. **Average shortest path length (ASPL)**
 For u and v in V , the *pairwise distance* $d(u, v)$ is the number of edges in the shortest path from u to v ; $d(u, v) = \infty$ iff there is no path from u to v (where ∞ is some number greater than $|E|$). The ASPL is

$$\frac{\sum_{d(u,v) < \infty} d(u, v)}{|V| \times (|V| - 1)}.$$

7. Effective diameter [21]

The effective diameter is the smallest $k \in N$ that is greater than 90% of all pairwise distances that satisfy $d(u, v) < \infty$.

4.2 Measuring Similarity

For a scalar graph property α , let α_G denote the α value for G and $\alpha_{\tilde{G}}^{(i)}$ denote the α value for \tilde{G} constructed with algorithm $\mathcal{A}^{(i)}$. We can compare $\mathcal{A}^{(1)}$ and $\mathcal{A}^{(2)}$ by the absolute difference $|\alpha_{\tilde{G}}^{(1)} - \alpha_G|$ or the relative difference $|\alpha_{\tilde{G}}^{(1)} - \alpha_G|/\alpha_G$. These are equivalent since

$$|\alpha_{\tilde{G}}^{(1)} - \alpha_G| < |\alpha_{\tilde{G}}^{(2)} - \alpha_G| \iff \frac{|\alpha_{\tilde{G}}^{(1)} - \alpha_G|}{\alpha_G} < \frac{|\alpha_{\tilde{G}}^{(2)} - \alpha_G|}{\alpha_G}$$

However, an α like effective diameter is an integer, whereas a property like average clustering coefficient has $\alpha < 1$. Some information on α_G is thus lost if we plot relative differences, so we will plot absolute differences instead.

For a degree distribution $f : N^d \rightarrow [0, 1]$, we follow Leskovec and Faloutsos [21] and use a Kolmogorov-Smirnov (KS) D-statistic to measure the difference between distributions f_G and $f_{\tilde{G}}$. For $d = 1$, the statistic is defined as

$$\sup_x |F_G(x) - F_{\tilde{G}}(x)|$$

where F_G and $F_{\tilde{G}}$ are the cumulative distribution functions (cdf) for f_G and $f_{\tilde{G}}$. For $d > 1$, defining the cdf is not straightforward, since there are $2^d - 1$ possibilities. In this paper, we adopt Fasano and Franceschini’s computationally efficient variant [10] of the KS D-statistic.

4.3 Algorithms

We compare GSCALER to state-of-art algorithms (for graph sampling, generative models, and database scaling) that have been widely used as baselines for comparison.

- In Random Walk with Escaping (RW), a starting node v_0 is chosen uniformly at random. Each step in the random walk samples an unvisited neighbor uniformly at random, and there is a probability 0.8 (following [21]) that the walk restarts at v_0 . If the walk reaches a dead end, the walk restarts with a new v_0 .
- In Forest Fire (FF) [21], a v_0 is similarly chosen. At each step, first choose a positive integer y that is geometrically distributed with mean $p_f(1 - p_f)$, and let $x = \lceil y \times c \rceil$, $c \in [0, 1]$. (We follow Leskovec and Faloutsos and set $p_f = 0.7$ and $c = 1$.) Pick uniformly at random neighbors w_1, \dots, w_x that are not yet sampled, then recursively repeat these steps at each w_i .
- In Stochastic Kronecker Graph (SKG) [20], SKG first trains a N_1 by N_1 matrix K_1 , where N_1 is typically set as 2. Then recursively multiply K_1 through Kronecker product. Thus, d multiplication of Kronecker product results in a graph of N_1^d nodes. In our experiment, we use the N_1^d closest to \tilde{n} as the target number \tilde{n} .
- *UpSizeR* was designed to synthetically scale a relational dataset by maintaining the degree distribution [33]. However, *UpSizeR* does not allow free choice of \tilde{m} . For our experiments, we transform the graph to relational tables so *UpSizeR* can scale it.

4.4 Datasets

We pick 2 real directed graphs from Stanford’s collection of networks [24]. They are large enough that it makes sense for scaling down, but small enough for global properties like diameter to be determined in reasonable time. These two graphs were also used by previous authors [20–22, 25].

- *Epinions* ($|V| = 75879$, $|E| = 508837$) for the website Epinions.com, where an edge (x, y) indicates user x trusts user y .
- *Slashdot* is a website for technology-related news, where users tag others as friend or foe. The graph contains friend/foe links between the users of Slashdot. The dataset *Slashdot0811* ($|V| = 77360$, $|E| = 828161$) was from November 2008.

Given the space constraint, we choose to compare more properties for 2 graphs, instead of comparing fewer properties for more graphs.

5. RESULTS AND DISCUSSION

All experiments are done on a Linux machine with 128GB memory and AMD Opteron 2.3GHz processor. For *SKG*, we use the C++ implementation [24]. For *UpSizeR*, we use the authors’ C++ implementation¹. For *FF*, *RW* and *GSCALER*, we implemented them in Java.

These algorithms use the number of nodes n to specify sample size or scale factor, so we define $s = \tilde{n}/n$. In our experiments, we set $s = \frac{1}{5}, \frac{1}{7.5}, \frac{1}{10}, \frac{1}{12.5}, \frac{1}{15}, \frac{1}{17.5}, \frac{1}{20}$ for scaling down, and $s = 2, 3, 4, 5, 6$ for scaling up.

GSCALER allows the user to specify the number of edges \tilde{m} . However, an \tilde{m} that is arbitrarily small or arbitrarily large will make it impossible for \tilde{G} to be similar to G . To be fair, we choose an \tilde{m} for GSCALER that yields the best results. We will revisit this issue in Sec.6.

For each s value, we run each algorithm 10 times (using different seeds) on each dataset. The average of these 10 runs is then plotted as one data point.

5.1 Execution Time

For a fair comparison, we exclude the *I/O* time for all algorithms.

Execution time for *SKG* has two parts: training time and running time. *SKG* needs to train the graph initiator matrix K_1 , where K_1 is a 2 by 2 matrix in our case; K_1 can be pre-computed. After K_1 is trained, *SKG* uses K_1 to generate a graph with 2^k nodes.

To get a better understanding of *SKG*’s time complexity, we plot both training time and running time. *SKG-Train* represents the time needed for training K_1 , while *SKG-Run* represents the running time of graph generation given K_1 .

Fig.4 and Fig.5 show the execution time for all algorithms using log scale.

For both datasets, *SKG-Train* is very large for training the graph initiator K_1 . However, after K_1 is trained, graph generation is fast (seconds), so *SKG-Run* is small. That aside, GSCALER has the smallest execution time, which is faster than *SKG-Train* by about 2 orders of magnitude, and faster than *RW*, *FF*, *UpSizeR* by about 1 order of magnitude.

¹<http://www.comp.nus.edu.sg/~upsizer/>

Figure 4: Execution time (log scale) for *Slashdot*. FF and RW do not work for $s > 1$.

5.2 Theoretical Bounds of Degree Distribution

Before looking at the similarity comparison, we first show theoretically that GSCALER performs well on varying \tilde{m} and \tilde{n} for indegree/outdegree distribution. To save space, we just consider indegree distribution throughout this section. The proof for the outdegree distribution is similar.

THEOREM 3. *Given original graph G 's indegree distribution is f_{in} , and GSCALER scales G to \tilde{G} , where \tilde{m} and \tilde{n} scale by the same ratio s . Then, $E[D(f_{in}, \tilde{f}_{in})] = 0$.*

PROOF. As explained in Sec.3.2, GSCALER scales S_{in} with the following criterion:

$$E[ct_{\tilde{S}_{in}}(x)] = ct_{S_{in}}(x) \times \frac{\tilde{n}}{n}$$

Now, consider the current scaled number of nodes $|\tilde{V}|$ and number of edges $|\tilde{E}|$. After node scaling,

$$\begin{aligned} E[|\tilde{V}|] &= E[\sum_x ct_{\tilde{S}_{in}}(x)] = \sum_x E[ct_{\tilde{S}_{in}}(x)] = \sum_x ct_{S_{in}}(x) \times s \\ &= n \times s = \tilde{n}. \end{aligned}$$

$$\begin{aligned} E[|\tilde{E}|] &= E[\sum_x ct_{\tilde{S}_{in}}(x) \times x] = \sum_x E[ct_{\tilde{S}_{in}}(x) \times x] \\ &= \sum_x E[ct_{\tilde{S}_{in}}(x)] \times x = \sum_x ct_{S_{in}}(x) \times s \times x \\ &= \sum_x ct_{S_{in}}(x) \times x \times s = m \times s = \tilde{m}. \end{aligned}$$

Hence, no *edge adjustment* is expected in Sec.3.2. Thus,

$$\forall x, E[\tilde{f}_{in}(x) - f_{in}(x)] = 0.$$

Consequently, $E[D(f_{in}, \tilde{f}_{in})] = 0$. \square

However, a GSCALER user may want to have a \tilde{G} with average degree different from G , i.e. \tilde{m} and \tilde{n} scale by different factors. In this case, GSCALER can still produce a similar degree distribution with small and bounded error.

THEOREM 4. *Given an original graph G 's indegree distribution is f_{in} , and GSCALER scales G to \tilde{G} , where $\tilde{n} = n \times s$, $\tilde{m} = m \times s \times (1 + r)$ and $r \neq 0$. Then,*

$$E[D(f_{in}, \tilde{f}_{in})] \leq \frac{2m|r|}{n \times d^*}$$

where d^* is approximately the largest degree of G .

PROOF. As shown in the proof of *Theorem 3*, after node scaling, $E[|\tilde{V}|] = n \times s = \tilde{n}$ and $E[|\tilde{E}|] = m \times s \neq \tilde{m}$.

Figure 5: Execution time (log scale) for *Epinions*. FF and RW do not work for $s > 1$.

Hence, *edge adjustment* is needed, as stated in Sec.3.2. In total, we are expecting $m \times s \times (1 + r)$ edges. Hence, $|m \times rs|$ edges are expected to be added/removed. We refer to $ct_{\tilde{S}_{in}}(x)$ as $ct(x)$ if there is no ambiguity.

Consider $r > 0$, so $m \times rs$ edges are to be added. This is done by the edge adjustment operation as stated in Algo.2: (i) $ct(l) -$, $ct(h) +$, (ii) $l +$, $h -$. The net effect is to add $h - l$ edges per adjustment.

Let d_m be the maximum degree of G . We assume l is initiated as 0, while h is initialized as d_m .

Case $ct(l) > 0$ for all the first k adjustment:

Then GSCALER will add

$$d_m, d_m - 2, d_m - 4, \dots, d_m - [(k - 1) \bmod \lceil \frac{d_m}{2} \rceil] \times 2 \quad (20)$$

edges for the first k adjustments. Let T_k be the total number of edges added by first k adjustments, then

$$T_k \geq \frac{d_m}{2} \times k \quad (21)$$

Since $m \times rs$ edges are expected to be added, the expected number of adjustments k satisfies

$$k \leq \frac{m \times rs}{\frac{d_m}{2}} = \frac{2m \times rs}{d_m} \quad (22)$$

Moreover, each edge adjustment changes \tilde{f}_{in} by

- (i) decrementing $\frac{1}{n}$ for some $\tilde{f}_{in}(x_i)$, where $x_i < \frac{d_m}{2}$
- (ii) incrementing $\frac{1}{n}$ for some $\tilde{f}_{in}(x_j)$, where $x_j > \frac{d_m}{2}$

Thus, the expected total decremental changes made to \tilde{f}_{in} is $\frac{1}{n} \times k$. By Eq.22,

$$\frac{1}{n} \times k \leq \frac{1}{n} \times \frac{2m \times rs}{d_m} = \frac{2m \times rs}{sn \times d_m} = \frac{2mr}{n \times d_m} \quad (23)$$

Since $D(f_{corr}, \tilde{f}_{corr})$ measures largest difference between the cumulative function of f_{corr} , \tilde{f}_{corr} . Hence, by Eq.23,

$$E[D(f_{corr}, \tilde{f}_{corr})] \leq \frac{2mr}{n \times d^*}, \text{ where } d^* = d_m \quad (24)$$

Case $\exists l_j, ct(l_j) = 0$. Assume at the i th adjustment, $ct(l_0) = 0$ for some l_0 , where i is the smallest.

Then GSCALER shifts l to $l_0 + 1$, and try to decrease $ct(l_0 + 1)$. Assume $ct(l_0 + 1) > 0$, then we can do $ct(l_0 + 1) -$.

1. $l_0 + 1 \neq h$: By Eq.20, the number of edges added at i th step is $d_m - [(i - 1) \bmod \lceil \frac{d_m}{2} \rceil] \times 2 - 1$. Hence, $T_i = T_{i-1} + d_m - [(i - 1) \bmod \lceil \frac{d_m}{2} \rceil] \times 2 - 1$. By Eq.21,

$$T_i + 1 \geq \frac{d_m}{2} \times i \quad (25)$$

Then, $T_i \geq \frac{d_m}{2} \times i - 1 = \frac{d_m-1}{2} \times i + (\frac{i}{2} - 1)$
 Since $T_1 = d_m - 1 \geq \frac{d_m-1}{2}$, then $T_i \geq \frac{d_m-1}{2} \times i \forall i \in N$

2. $l_0 + 1 = h$: Then l will be reset to 0, and h will be reset to d_m , so the number of edges at i th adjustment is obviously larger than $d_m - [(i-1) \bmod \lceil \frac{d_m}{2} \rceil] \times 2 - 1$. Hence, Eq.25 will hold as well.

Therefore, during the first k adjustments, if we encounter w different l_0, l_1, \dots, l_{w-1} , such that $ct(l_j) = 0, \forall 0 \leq j < w$, then by mathematical induction, one can still conclude that

$$T_i \geq \frac{d_m - w}{2} \times i.$$

Hence, let $d^* = d_m - w$ and follow the proof after Eq.21; then $E[D(f_{corr}, \tilde{f}_{corr})] \leq \frac{2mr}{n \times d^*}$, where d^* is close to d_m in general.

The proof for $r < 0$ is similar \square

5.3 Experimental Results

All figures in this section (except Figs.7, 9, 11,12) plot the similarity measures (Sec. 4.2) comparing G and \tilde{G} , where

- the horizontal axis is scale factor $s = \frac{\tilde{n}}{n}$;
- the vertical axis is KS D-statistic for indegree, outdegree and bidegree distributions;
- the vertical axis is absolute error for the other 5 properties (effective diameter, largest SCC ratio, etc.);
- the true value for all datasets' graph properties are provided above each figure;
- we choose \tilde{m} to give best results for GSCALER; the other algorithms do not allow a free choice of \tilde{m} .

We first look at *scaling down* for all the algorithms. As mentioned in Sec.1, scaling down in GSP has an objective that is different from graph sampling. However, we use graph sampling algorithms for comparison because GSP is a new problem, so there is no other algorithms for comparison except *UpSizeR* and *SKG*.

Figure 6: KS-D statistics for Indegree Distribution

Figure 7: Indegree Distribution Plot

Figure 8: KS-D statistics for Outdegree Distribution

Figure 9: Outdegree Distribution Plot

5.3.1 Indegree Distribution

For the indegree distribution, Fig. 6 shows that both GSCALER and *UpSizeR* perform very well for *Slashdot*, with error < 0.01 . For *Epinions*, *UpSizeR* has an error of 0.05 on average, whereas GSCALER again has a small error < 0.01 .

For more details, Fig. 7 plots the indegree distribution for $s = 0.2$, where the x-axis is the indegree, and the y axis is the ratio of nodes having that indegree. We only show the plot up to *indegree* = 15, which covers more than 87% of all nodes.

The plot shows that GSCALER and *UpSizeR* mimics G 's indegree distribution very well. Although all algorithms produce power law shaped distributions, only *UpSizeR* and GSCALER give a close fit for the empirical distribution.

5.3.2 Outdegree Distribution

For the outdegree distribution, Fig. 8 similarly shows that both GSCALER and *UpSizeR* perform very well for *Slashdot*, with error < 0.03 on average. For *Epinions*, *UpSizeR* has an error of 0.05 on average, whereas GSCALER still has an error < 0.01 .

The outdegree distributions are plotted in Fig. 9. We observe that GSCALER and *UpSizeR* also closely match G 's outdegree distribution. Again, although all algorithms produce power law shaped distributions, *UpSizeR* and GSCALER give the best fit for the empirical outdegree distribution.

5.3.3 Bidegree Distribution

Figure 10: KS-D statistics for Bidegree Distribution

Figure 11: Bidegree distribution for *Slashdot*

Figure 12: Bidegree distribution for *Epinions*

Even though *UpSizeR* matches the empirical indegree and outdegree distributions, it is not able to capture the bidegree distribution that describes the correlation between indegree and outdegree. Such correlation is especially important for social network graphs. For example, in *Epinions*, the number of people he/she trusts and the number of people who trust him/her are correlated. As shown in Fig.10, only GSCALER captures such correlation very well.

For a detailed look at the bidegree distributions, we give 2-dimensional plots Fig. 11 and Fig. 12. We transform the bidegree distribution to a $k \times k$ matrix B . Each cell i, j represents the portion of nodes with bidegree (i, j) . In other words, $B[i, j] = f_{bi}(i, j)$. When visualizing B , we use a gray scale intensity plot for cell i, j to indicate $B[i, j]$. The larger f_{bi} is, the darker the cell (i, j) is. In our case, we set $k = 50$ which covers more than 90% of total nodes.

Fig. 11 and Fig. 12 show *indegree* is positively correlated to *outdegree*. For both *Slashdot* and *Epinions*, GSCALER is the best algorithm in capturing this indegree/outdegree correlation. We also observe that *UpSizeR* tends to have indegree and outdegree negatively correlated. *SKG* has very concentrated and similar-shaped plots for both datasets. We suspect this is because of the self-similar matrix operation, Kronecker product. For *FF*, it captures the bidegree correlation for *Slashdot*'s bidegree, but not for *Epinions*.

Figure 13: Absolute Error for Effective Diameter

Figure 14: Absolute Error for Average CC

5.3.4 Effective Diameter

Fig. 13 shows that, for *Slashdot*, GSCALER produces exactly the real effective diameter; for *Epinions*, it produces an effective diameter with an absolute error no larger than 1. Overall, GSCALER, *FF*, *SKG* are the best algorithms in producing similar effective diameters.

5.3.5 Average Clustering Coefficient

For both datasets, GSCALER significantly reduces the error for average clustering coefficient. Fig. 14 shows that, for *Slashdot*, the average error for the other algorithms are between 0.03 and 0.045. This corresponds to a relative error of 60% to 90%. However, GSCALER only has an absolute error 0.005 on average, which corresponds to a relative error $< 10\%$. Similarly, for *Epinions*, GSCALER also improves the relative error from 70% to 10% on average.

5.3.6 Largest SCC Ratio

Figure 15: Absolute Error for Largest SCC Ratio

Figure 16: Absolute Error for ASPL

For largest SCC ratio, Fig. 15 shows that *FF*, *UpSizeR*, and GSCALER have the best performance for *Slashdot*. For *Epinions*, *SKG* is the best performing algorithm, whereas GSCALER only loses to *SKG* by an error < 0.01 .

Note that, GSCALER and *FF* are the best performing algorithms which produce best similar largest SCC ratio for both datasets on average.

5.3.7 Average Shortest Path Length

Fig. 16 shows that GSCALER is the best algorithm in producing similar *ASPL* for the scaled graph.

For *Slashdot*, GSCALER has relative error $< 10\%$, whereas the second best performing algorithm *UpSizeR* has the average relative error 40%

For *Epinions*, GSCALER is the most stable and accurate algorithm, with a consistent absolute error < 0.25 . *RW* performs well for large s , but does badly for small s .

5.3.8 Scaling Up

To save space, Fig.17 plots performance of both *Slashdot* and *Epinions* for each graph property.

Similar to scaling down, GSCALER improves the accuracy of indegree/outdegree/bidegree distribution significantly. For effective diameter, GSCALER and *SKG* are the best performing algorithms. GSCALER is the best algorithm which produces the most accurate results for average clustering coefficient, largest SCC ratio, and average shortest path length.

5.3.9 Summary of Comparisons

For indegree, outdegree and bidegree distributions, GSCALER reduces the error from about 0.1 for the other algorithms to about 0.01. This is expected since GSCALER uses f_{bi} to construct \tilde{G} , and agrees with the theoretical bound in Sec. 5.2.

GSCALER only uses $\mathcal{P}_{sub} = \{f_{bi}, f_{corr}\}$ to construct \tilde{G} , but measures similarity to G with a larger set \mathcal{P} of both local and global properties listed in Sec. 4.1. The results show that enforcing \mathcal{P}_{sub} suffices to induce similarity for \mathcal{P} .

6. LIMITATION

Unlike the other algorithms, a user can choose both \tilde{n} and \tilde{m} for GSCALER. Table 5 illustrates GSCALER's accuracy for *Slashdot*, using different \tilde{n} and \tilde{m} .

However, GSCALER cannot guarantee similarity for arbitrary choices of \tilde{n} and \tilde{m} — the error bound in *Theorem 4* becomes loose for large $|r|$. For example, if $n = 1000$ and $m = 5000$, but $\tilde{n} = 2000$ and $\tilde{m} = 500000$, one cannot expect to find any \tilde{G} similar to G .

There is a Densification Law [23] that says, if G_1, G_2, G_3, \dots , are snapshots of a growing graph, then

$$E(G_i) \propto V(G_i)^\alpha \quad \text{for some } 1 \leq \alpha \leq 2$$

If \tilde{G} follows such a law, then $(\tilde{m}/m) = (\tilde{n}/n)^\alpha$. If $\tilde{n} = sn$ and $\tilde{m} = (1+r)sm$, then

$$\frac{\tilde{m}}{\tilde{n}^\alpha} = \frac{(1+r)sm}{(sn)^\alpha} = \frac{m}{n^\alpha} \frac{1+r}{s^{(\alpha-1)}},$$

Therefore, for \tilde{G} to follow the Densification Law, the user must choose $r > 0$ for $s > 1$, and $r < 0$ for $s < 1$. In other words, $\tilde{m} > m\tilde{n}/n$ for $\tilde{n}/n > 1$, and $\tilde{m} < m\tilde{n}/n$ for $\tilde{n}/n < 1$.

Note that modeling the evolution of n and m is an interesting problem that is relevant, but orthogonal to GSP.

Slashdot		Effective Diameter	Largest SCC	ASPL	CC
$n = 77360$	$m = 828161$	5	0.909	3.74	0.052
$\tilde{n} = 4421$	$\tilde{m} = 32179$	5	0.916	3.59	0.058

Table 5: Gscaler accuracy for different \tilde{n} and \tilde{m} .

7. CONCLUSION

We considered the problem of synthetically scaling a given graph. Our solution GSCALER first breaks G into pieces, scales them, then merges them using the degree and correlation functions from G .

Different from previous approaches, GSCALER gives user a choice for \tilde{n} and \tilde{m} . We proved that GSCALER does not produce multiple edges between two nodes, and has a small distribution error even when the average degree of \tilde{G} differs from the original graph G .

Experiments with 2 well-known real datasets show that the \tilde{G} constructed by GSCALER is more similar to G for most properties than random walk, forest fire, *UpSizeR* and Stochastic Kronecker Graph.

Our current work aims to extend GSCALER to scale relational databases by representing the tables as graphs.

ABSTRACT

The work on large-scale graph analytics to date has largely focused on the study of static properties of graph snapshots. However, a static view of interactions between entities is often an oversimplification of several complex phenomena like the *spread of epidemics*, *information diffusion*, *formation of online communities*, and so on. Being able to find temporal interaction patterns, visualize the evolution of graph properties, or even simply compare snapshots across time, adds significant value in reasoning over graphs. However, due to the lack of underlying data management support, an analyst today has to manually navigate the added temporal complexity of dealing with large evolving graphs. In this paper, we present a system, called *Historical Graph Store*, that enables users to store large volumes of historical graph data and to express and run complex temporal graph analytical tasks against that data. It consists of two key components: (1) a *Temporal Graph Index* (TGI), that compactly stores large volumes of historical graph evolution data in a partitioned and distributed fashion – TGI also provides support for retrieving snapshots of the graph as of any timepoint in the past or evolution histories of individual nodes or neighborhoods; and (2) a *Temporal Graph Analysis Framework* (TAF), for expressing complex temporal analytical tasks and for executing them in an efficient and scalable manner using Apache Spark. Our experiments demonstrate our system's efficient storage, retrieval and analytics across a wide variety of queries on large volumes of historical graph data.

1. INTRODUCTION

Graphs are useful in capturing behavior involving interactions between entities. Several processes are naturally represented as graphs – social interactions between people, financial transactions, biological interactions among proteins, geospatial proximity of infected livestock, and so on. Many problems based on such graph models can be solved using well-studied algorithms from graph theory or network science. Examples include finding driving routes by computing shortest paths on a network of roads, finding user communities through dense subgraph identification in a social network, and many others. Numerous graph data management systems have been developed over the last decade, including special-

ized graph database systems like Neo4j, Titan, etc., and large-scale graph processing frameworks such as GraphLab [27], Pregel [29], Giraph, GraphX [12], GraphChi [24], etc.

However much of the work to date, especially on cloud-scale graph data management systems, focuses on managing and analyzing a single (typically, current) static snapshot of the data. In the real world, however, interactions are a dynamic affair and any graph that abstracts a real-world process changes over time. For instance, in online social media, the friendship network on Facebook or the “follows” network on Twitter change steadily over time, whereas the “mentions” or the “retweet” networks change much more rapidly. Dynamic cellular networks in biology, evolving citation networks in publications, dynamic financial transactional networks, are few other examples of such data. Lately, we have seen an increasing merit in dynamic modeling and analysis of network data to obtain crucial insights in several domains such as cancer prediction [38], epidemiology [15], organizational sociology [16], molecular biology [9], information spread on social networks [26] amongst others.

In this work, our focus is on providing the ability to analyze and to reason over the entire history of the changes to a graph. There are many different types of analyses of interest. For example, an analyst may wish to study the evolution of well-studied static graph properties such as centrality measures, density, conductance, etc., over time. Another approach is through the search and discovery of temporal patterns, where the events that constitute the pattern are spread out over time. Comparative analysis, such as juxtaposition of a statistic over time, or perhaps, computing aggregates such as *max* or *mean* over time, possibly gives another style of knowledge discovery into temporal graphs. Most of all, a primitive notion of just being able to access past states of the graphs and performing simple static graph analysis, empowers a data scientist with the capacity to perform analysis in arbitrary and unconventional patterns.

Supporting such a diverse set of temporal analytics and querying over large volumes of historical graph data requires addressing several data management challenges. Specifically, there is a want of techniques for storing the historical information in a compact manner, while allowing a user to retrieve graph snapshots as of any time point in the past or the evolution history of a specific node or a specific neighborhood. Further, the data must be stored and queried in a distributed fashion to handle the increasing scale of the data. There is also a need for an expressive, high-level, easy-to-use programming framework that will allow users to specify complex temporal graph analysis tasks, while ensuring those tasks can be executed efficiently in a data-parallel fashion across a cluster.

In this paper, we present a graph data management system, called *Historical Graph Store* (HGS), that provides an ecosystem for managing and analyzing large historical traces of graphs. HGS con-

sists of two key distinct components. First, the *Temporal Graph Index (TGI)*, is an index that compactly stores the entire history of a graph by appropriately partitioning and encoding the differences over time (called *deltas*). These deltas are organized to optimize the retrieval of several temporal graph primitives such as neighborhood versions, node histories, and graph snapshots. TGI is designed to use a distributed key-value store to store the partitioned deltas, and can thus leverage the scalability afforded by those systems (our implementation uses Apache Cassandra¹ key-value store). TGI is a tunable index structure, and we investigate the impact of tuning the different parameters through an extensive empirical evaluation. TGI builds upon our prior work on DeltaGraph [21], where the focus was on retrieving individual snapshots efficiently; TGI extends DeltaGraph to support efficient retrieval of subgraphs instead of only full snapshots, retrieval of histories of nodes or subgraphs over past time intervals, and features a highly scalable design over DeltaGraph.

The second component of HGS is a *Temporal Graph Analysis Framework (TAF)*, which provides an expressive framework to specify a wide range of temporal graph analysis tasks. TAF is based on a novel set of *temporal graph operands* and *operators* that enable parallel execution of the specified tasks at scale in a cluster environment. The execution engine is implemented on Apache Spark [40], a large-scale in-memory cluster computing framework.

Outline: The rest of the paper is organized as follows. In Section 2, we survey the related work on graph data stores, temporal indexing, and other topics relevant to the scope of the paper. In Section 3, we provide a sketch of the overall system, including key aspects of the underlying components. We then present TGI and TAF in detail in Sections 4 and 5, respectively. In Section 6, we provide an empirical evaluation, and conclude with a summary and a list of future directions in Section 7.

2. RELATED WORK

In the recent years, there has been much work on graph storage and graph processing systems and numerous systems have been designed to address various aspects of graph data management. Some examples include Neo4J, Titan², GBase [19], Pregel [29], Giraph, GraphX [12], GraphLab [27], and Trinity [36]. These systems use a variety of different models for representation, storage, and querying, and there is a lack of standardized or widely accepted models for the same. Most graph querying happens through programmatic access to graphs in languages such as Java, Python or C++. Graph libraries such as Blueprints³ provide a rich set of implementations for graph theoretic algorithms. SPARQL [33] is a language used to search patterns in linked data. It works on an underlying RDF representation of graphs. T-SPARQL [13] is a temporal extension of SPARQL. He et al. [17], provide a language for finding sub-graph patterns using a graph as a query primitive. Gremlin⁴ is a graph traversal language over the property graph data model, and has been adopted by several open-source systems. For large-scale graph analysis, perhaps the most popular framework is the vertex-centric programming framework, adopted by Giraph, GraphLab, GraphX, and several other systems; there have also been several proposals for richer and more expressive programming frameworks in recent years. However, most of these prior systems largely focus on analyzing a single snapshot of the graph data, with very little support for handling dynamic graphs, if any.

A few recent papers address the issues of storage and retrieval in dynamic graphs. In our prior work, we proposed DeltaGraph [21], an index data structure that compactly stores the history of all changes in a dynamic graph and provides efficient snapshot reconstruction. G* [25] stores multiple snapshots compactly by utilizing commonalities. ImmortalGraph [30] is an in-memory system for processing dynamic graphs, with the objectives of shared storage and computation for overlapping snapshots. Ghrab et al. [11] provide a system of network analytics through labeling graph components. Gedik et al. [10], describe a block-oriented and cache-enabled system to exploit spatio-temporal locality for solving temporal neighborhood queries. Koloniari et al. [23] also utilize caching to fetch selective portions of temporal graphs they refer to as partial views. LLAMA [28] uses multiversioned arrays to represent a mutating graph, but their focus is primarily on in-memory representation. There is also recent work on streaming analytics over dynamic graph data [8, 7], but it typically focuses on analyzing only the recent activity in the network (typically over a sliding window).

Temporal graph analytics is an area of growing interest. Evolution of shortest paths in dynamic graphs has been studied by Huo et al. [18], and Ren et al. [34]. Evolution of community structures in graphs has been of interest as well [5, 14]. Change in page rank with evolving graphs [3], and the study of change in centrality of vertices, path lengths of vertex pairs, etc. [32], also lie under the larger umbrella of temporal graph analysis. Ahn et al. [1] provide a taxonomy of analytical tasks over evolving graphs. Barrat et al. [4], provide a good reference for studying several dynamic processes modeled over graphs. Our system significantly reduces the effort involved in building and deploying such analytics over large volumes of graph data.

Temporal data management for relational databases was a topic of active research in the 80s and early 90s. Snapshot index [39] is an I/O optimal solution to the problem of snapshot retrieval for transaction-time databases. Salzberg and Tsotras [35] present a comprehensive survey of temporal data indexing techniques, and discuss two extreme approaches to supporting snapshot retrieval queries, referred to as the *Copy* and *Log* approaches. While the copy approach relies on storing new copies of a snapshot upon every point of change in the database, the log approach relies on storing everything through changes. Their hybrid is often referred to as the *Copy+Log* approach. We omit a detailed discussion of the work on temporal databases, and refer the interested reader to a representative set of references [37, 31, 35]. Other data structures, such as Interval Trees [2] and Segment trees [6] can also be used for storing temporal information. Temporal aggregation in scientific array databases is another related topic of interest, but the challenges there are significantly different. Kaufmann et al. [20] propose an in-memory index in SAP HANA that addresses temporal aggregation, joins, and snapshot construction. The applicability of temporal relational data management techniques to graphs is restricted due to lack of (efficient) support for graph specific retrieval such as fetching neighborhoods, or histories of nodes over time. Our work in this paper focuses on techniques for a wide variety of temporal graph retrieval and analysis on entire graph histories that are primarily stored on disk.

3. OVERVIEW

In this section, we introduce key aspects related to HGS. We begin with the data model, followed by the key challenges and concluding with an overview of the system.

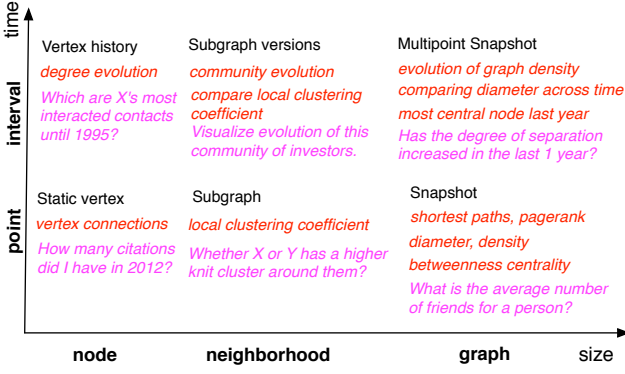

Figure 1: The scope of temporal graph analytics can be represented across two different dimensions - time and entity. The chart lists retrieval tasks (black), graph operations (red), example queries (magenta) at different granularities of time and entity size.

3.1 Data Model

Under a discreet notion of time, a time-evolving graph $G^T = (V^T, E^T)$ may be expressed as a collection of graph *snapshots* over different time points, $\{G^0 = (V^0, E^0), G^1, \dots, G^T\}$. The vertex set V^i for a snapshot consists of a set of vertices (nodes), each of which has a unique identifier (constant over time), and an arbitrary number of key-value attribute pairs. The edge sets E^i consist of edges that each contain references to two valid nodes in the corresponding vertex set V^i , information about the direction of the edge, and an arbitrary list of key-value attribute pairs. A temporal graph can also be equivalently described by a set of changes to the graph over time. We call an atomic change at a specific timepoint in the graph an *event*. The changes could be structural, such as the addition or the deletion of nodes or edges, or be related to attributes such as an addition or a deletion or a change in the value of a node or an edge attribute. For instance, a new user joining the Facebook social network corresponds to an event of node creation; connecting to another user is an event of edge creation; changing location or posting an update are events of change and creation of attribute values, respectively. These approaches specified here as well as certain hybrids have been used in the past for the physical and logical modeling of temporal data. Our approach to temporal processing in this paper is best described using a *node-centric* logical model, i.e., the historical graph is seen as a collection of evolving vertices over time; the edges are considered as attributes of the nodes. This abstraction helps in our design of distributed storage of the graph and parallel execution of the analytical tasks.

3.2 Challenges

The nature of data management tasks in historical graph analytics can be categorized based on the scope of analysis using the dual dimensions of *time* and *entity* as illustrated with examples in Figure 1. The temporal scope of an analysis task can range from a single point in time to a long interval; the entity scope can range from a single node to the entire graph. While the diversity of analytical tasks provides a potential for a rich set of insights from historical graphs, it also poses several challenges in constructing a system that can perform those tasks. To the best of our knowledge, none of the existing systems address a majority of those challenges that are described below:

Compact storage with fast access: An natural tradeoff between index size and access latencies can be seen in the Log and Copy approaches for snapshot retrieval. Log requires minimal information

to encode the graph’s history, but incurs large reconstruction costs. Copy, on the other hand, provides direct access, but at the cost of excessive storage. The desirable index should consume space of the order of Log index but provide near direct access like Copy.

Time-centric versus entity-centric indexing: For *point* access such as past snapshot retrieval, a time-centric indexing such as DeltaGraph or Copy+Log is suitable. However, for version retrieval tasks such as retrieving a *node’s history*, entity-centric indexing is the correct choice. Neither of the indexing approaches, however, are feasible in the opposite scenarios. Given the diversity of access needs, we require an index that works well with both styles of lookup at the same time.

Optimal granularity of storage for different queries: Query latencies for a graph also depend on the size of chunks in which the data is indexed. While larger granularities of storage incur wasteful data read for “node retrieval”, a finely chunked graph storage would mean higher number of lookups and aggregation for a 2-hop neighborhood lookup. The physical and logical arrangement of data should take care of access needs at all granularities.

Coping with changing topology in a dynamic graph: It is evident that graph partitioning is inevitable in the storage and processing of large graphs. However, finding the appropriate strategy to maintain workable partitioning on a constantly *changing* graph is another challenge while designing a historical graph index.

Systematically expressing temporal graph analytics: A platform for expressing a wide variety of historical graph analytics requires an appropriate amalgam of temporal logic and graph theory. Additionally, utilizing a vast body of existing tools in network science is an engineering challenge and opportunity.

Appropriate abstractions for distributed, scalable analytics: Parallelization is key to scale up analytics for large graph datasets. It is essential that the underlying data-representations and operators in the analytical platform be designed for parallel computing.

3.3 System Overview

Figure 2 shows the architecture of our proposed Historical Graph Store. It consists of two main components:

Temporal Graph Index (TGI) records the entire history of a graph compactly while enabling efficient retrieval of several temporal graph primitives. It encodes various forms of differences (called *deltas*) in the graph, such as atomic events, changes in subgraphs over intervals of time, etc. It uses specific choices of graph partitioning, data replication, temporal compression and data placement to optimize the graph retrieval performance. TGI uses Cassandra, a distributed key-value store for the deltas. In Section 4, we describe the design details of TGI and the access algorithms.

Temporal Graph Analytics Framework (TAF) provides a *temporal node-centric* abstraction for specifying and executing complex temporal network analysis tasks. It helps the user analyze the history of the graph by means of simple yet expressive *temporal operators*. The abstraction of temporal graph through a *set of (temporal) nodes (SoN)* allows the framework to achieve computational scalability through distribution of tasks by node and time. TAF is built on top of Apache Spark to utilize its support for scalable, in-memory, cluster computation; TAF provides an option to utilize GraphX for static graph computation. We provide a Java and Python based library to specify the retrieval, computation and analysis tasks. In Section 5, we describe the details of the data and computational models, query processing, parallel data fetch aspects of the system, the analytical library along with a few examples.

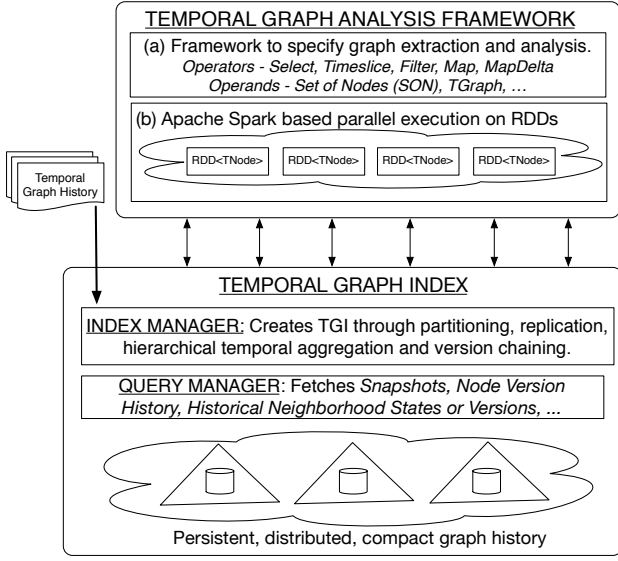

Figure 2: System Overview

4. TEMPORAL GRAPH INDEX

In this section, we investigate the issue of indexing temporal graphs. First, we introduce a *delta framework* to define any temporal index as a set of different changes or *deltas*. Using this framework, we are able to qualitatively compare the access costs and sizes of different alternatives for temporal graph indexing, including our proposed approach. We then present the Temporal Graph Index (TGI), that stores the entire history of a large evolving network in the cloud, and facilitates efficient parallel reconstruction for different graph primitives. TGI is a generalization of both entity and time-based indexing approaches and can be tuned to suit specific workload needs. We claim that TGI is the minimal index that provides efficient access to a variety of primitives on a historical graph, ranging from past snapshots to versions of a node or neighborhood. We also describe the key partitioning strategies instrumental in scaling to large datasets across a cloud storage.

4.1 Preliminaries

We start with a few preliminary definitions that help us formalize the notion of the delta framework.

DEFINITION 1 (STATIC NODE). A static node refers to the state of a vertex in a network at a specific time, and is defined as a set containing: (a) node-id, denoted I (an integer), (b) an edge-list, denoted E (captured as a set of node-ids), (c) attributes, denoted A , a map of key-value pairs.

A static edge is defined analogously, and contains the node-ids for the two endpoints and the edge direction in addition to a map of key-value pairs. Finally, a static graph component refers to either a static edge or a static node.

DEFINITION 2 (DELTA). A Delta (Δ) refers to either: (a) a static graph component (including the empty set), or (b) a difference, sum, union or intersection of two deltas.

Such a definition of delta helps express the change in a wider context than merely difference of graph states at two points. It helps us articulate several temporal graph indexes including TGI and Delta-Graph in a single framework.

DEFINITION 3 (CARDINALITY AND SIZE). The cardinality and the size of a delta are the unique and total number of static node or edge descriptions within it, respectively.

DEFINITION 4 (Δ SUM). A sum (+) over two deltas, Δ_1 and Δ_2 , i.e., $\Delta_s = \Delta_1 + \Delta_2$ is defined over graph components in the two deltas as follows: (1) $\forall gc_1 \in \Delta_1$, if $\exists gc_2 \in \Delta_2$ s.t. $gc_1.I = gc_2.I$, then we add gc_2 to Δ_s , (2) $\forall gc_1 \in \Delta_1$ s.t. $\nexists gc_2 \in \Delta_2$ s.t. $gc_1.I = gc_2.I$, we add gc_1 to Δ_s , and (3) analogously the components present only in Δ_2 are added to Δ_s .

Note that: $\Delta_1 + \Delta_2 = \Delta_2 + \Delta_1$ is not necessarily true due the order of changes. We also note that: $\Delta_1 + \emptyset = \Delta_1$, and $(\Delta_1 + \Delta_2) + \Delta_3 = \Delta_1 + (\Delta_2 + \Delta_3)$. Analogously, difference(-) is defined as a set difference over different components of the two deltas. $\Delta_1 - \phi = \Delta_1$ and $\Delta_1 - \Delta_1 = \phi$, are true, while, $\Delta_1 - \Delta_2 = \Delta_2 - \Delta_1$, does not necessarily hold.

DEFINITION 5 (Δ INTERSECTION). An intersection of two deltas is defined as a set intersection over the the components of two deltas. $\Delta_1 \cap \phi = \phi$, is true for any delta. Similarly, union of two deltas $\Delta_{\cup} = \Delta_1 \cup \Delta_2$, consists of all elements from Δ_1 and Δ_2 . The following is true for any delta: $\Delta_1 \cup \phi = \Delta_1$.

Next we discuss and define some specific types of deltas:

DEFINITION 6 (EVENT). An event is the smallest change that happens to a graph, i.e., addition or deletion of a node or an edge, or a change in an attribute value. An event is described around one time point. As a delta, an event concerning a graph component c , at time point t_e , is defined as the difference of state of c at and before t_e , i.e., $\Delta_{event}(c, t_e) = c(t_e) - c(t_e - 1)$.

DEFINITION 7 (EVENTLIST). An eventlist delta is a chronologically sorted set of event deltas. An eventlist's scope may be defined by the time duration, $(t_s, t_e]$, during which it defines all the changes that happened to the graph.

DEFINITION 8 (EVENTLIST PARTITION). An eventlist partition delta is a chronologically sorted set of event deltas pertaining to a set of nodes, P , over a given time duration, $(t_s, t_e]$.

DEFINITION 9 (SNAPSHOT). A snapshot, G^{t_a} is the state of a graph G at a time point t_a . As a delta, it is defined as the difference of the state of the graph at t_a from an empty set, $\Delta_{snapshot}(G, t_a) = G(t_a) - G(-\infty)$.

DEFINITION 10 (SNAPSHOT PARTITION). A snapshot partition is a subset of a snapshot. It is identified by a subset P of all nodes in graph, G at time, t_a . It consists of all nodes in G at t_a and all the edges whose at least one end-point lies in P at time, t_a .

4.2 Prior Techniques

The prior techniques for temporal graph indexing use changes or differences in various forms to encode time-evolving datasets. We can express them in the Δ -framework as follows. The **Log** index is equivalent to a set of all event deltas (equivalently, a single eventlist delta encompassing the entire history). The **Copy+Log** index can be represented as combination of: (a) a finite number of distinct snapshot deltas, and (b) eventlist deltas to capture the change between successive snapshots. Although we are not aware of a specific proposal for a **vertex-centric** index, however, a natural approach would be to maintain a set of eventlist partition deltas,

one for each node (with edge information replicated with the end-points). The **DeltaGraph** index, proposed in our prior work, is a tunable index with several parameters. For a typical setting of parameters, it can be seen as equivalent to taking a Copy+Log index, and replacing the *snapshot* deltas in it with another set of deltas constructed hierarchically as follows: for every k successive *snapshot* deltas, replace them with a single delta that is the intersection of those deltas and a set of difference deltas from the intersection to the original snapshots, and recursively apply this till you are left with a single delta.

Table 1 estimates the cost of fetching different graph primitives as the number and the cumulative size of deltas that need to be fetched for the different indexes. The first column shows an estimate of index storage space, which varies considerably across the techniques. For proofs, please refer to the extended version [22].

4.3 Temporal Graph Index: Definition

Given the above formalism, a Temporal Graph Index for a graph G over a time period $T = [0, t_c]$ is described by a collection of different deltas as follows:

- (a) Eventlist Partitions: A set of eventlist partition deltas, $\{E_{tp}\}$, where E_{tp} captures the changes during the time interval t belonging to partition p .
- (b) Derived Snapshot Partitions: Consider r distinct time points, t_i , where $1 \leq i \leq r$, $t_i \in T$. For each t_i , we consider l partition deltas, P_j^i , $1 < j < l$, such that $\cup_j P_j^i = G^{t_i}$. There exists a function that maps any node-id(I) in G^{t_i} to a unique partition-id(P_j^i), $f_i : I \rightarrow P_j^i$. With a collection of P_j^i over T as leaf nodes, we construct a hierarchical tree structure where a parent is the intersection of children deltas. The difference of each parent from its child delta is called as a *derived snapshot partition* and is explicitly stored. Note that P_j^i are not explicitly stored. This is the same as DeltaGraph, with the exception of partitioning.
- (c) Version Chain: For all nodes N in the graph G , we maintain a chronologically sorted list of pointers to all the references for that node in the delta sets described above (a and b). For a node I , this is called a *version chain* (denoted VC_I).

In short, the TGI stores *deltas* or *changes* in three different forms, as follows. The first one is the atomic changes in a chronological order through eventlist partitions. This facilitates direct access to the changes that happened to a part or whole of the graph at specified points in time. Secondly, the state of nodes at different points in time is stored indirectly in form of the derived snapshot partition deltas. This facilitates direct access to the state of a neighborhood or the entire graph at a given time. Thirdly, a meta index stores node-wise pointers to the list of chronological changes for each node. This gives us a direct access to the changes occurring to individual nodes. Figure 3(a) shows the arrangement of eventlist, snapshot and derived snapshot partition deltas. Figure 3(b) shows a sample version chain.

TGI utilizes the concept of temporal consistency which was optimally utilized by DeltaGraph. However, it differs from DeltaGraph in two major ways. First, it uses a partitioning for eventlists, snapshots or deltas instead of large monolithic chunks. Additionally, it maintains a list of version chain pointers for each node. The combination of these two novelties along with DeltaGraph's temporal compression generalizes the notion of entity-centric and time-centric indexing approaches in an efficient way. This can be seen by the qualitative comparison shown in Table 1 as well as empirical results in Section 6. Note that the particular design of TGI in the form of eventlist partitions and deltas, and version chain is not equivalent to two separate indexes, one with snapshots and eventlists and

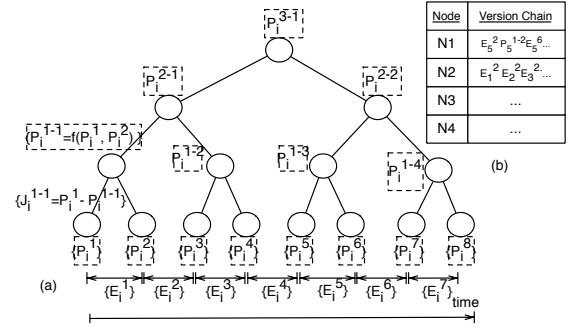

Figure 3: Temporal Graph Index representation: (a) TGI deltas partitions - eventlists, snapshots and derived snapshots. The (dashed) bounded deltas are not stored; (b) Version Chains.

the other with chronologically organized events per node. For instance, the latter is fairly inefficient to fetch temporal subgraphs or neighborhoods over time intervals.

4.4 TGI: Design and Architecture

In the previous subsection, we presented the logical description of TGI. We now describe the strategies for physical storage on a cloud which enables high scalability. In a distributed index, we desire that all graph retrieval calls achieve maximum parallelization through equitable distribution. A distribution strategy based on pure node-based key is good idea for snapshot style access, however, it is bad for a subgraph history style of access. A pure time-based key strategy on the other hand, has complementary qualities and drawbacks. An important related challenge for scalability is dealing with two different skews in a temporal graph dataset – temporal and topological. They refer to the uneven density of graph activity over time and the uneven edge density across regions of the graph, respectively. Another important aspect to note is that for a retrieval task, it is desirable that all the deltas needed for a fetch operation that are present on a particular machine be proximally located to minimize latency of lookups⁵. Based on the above constraints and desired properties, we describe the physical layout of TGI as follows:

1. The entire history of the graph is divided into *time spans*, keeping the number of changes to the graph consistent across different time spans, $f_t : e.time \rightarrow tsid$, where e is the event and $tsid$ is the unique identifier for the time span.
2. A graph at any point is horizontally partitioned into a fixed number of *horizontal partitions* based upon a random function of the node-id, $f_h : nid \rightarrow sid$, where nid is the node-id and sid is unique identifier of for the horizontal partition.
3. The partition deltas (including eventlists) are stored as a key-value pairs, where the delta-key is composed of $\{tsid, sid, did, pid\}$, where did is a delta-id, and pid is the partition-id of the partition.
4. The placement-key is defined as a subset of the composite deltas key described above, as $\{tsid, sid\}$, which defines the chunks in which data is placed across a set of machines on a cluster. A combination of the $tsid$ and sid ensure that a large fetch task, whether snapshot or version oriented, seeks data distributed across the cluster and not just one machine.

⁵In general, this depends on the underlying storage mechanism. The physical placement of deltas is irrelevant for an in-memory store, but significant for an on-disk store due to seek times.

	Index Size	Snapshot		Static Vertex		Vertex versions		1-hop		1-hop Versions	
		$\sum_{\Delta} \Delta $	$\sum_{\Delta} 1$	$\sum_{\Delta} \Delta $	$\sum_{\Delta} 1$	$\sum_{\Delta} \Delta $	$\sum_{\Delta} 1$	$\sum_{\Delta} \Delta $	$\sum_{\Delta} 1$	$\sum_{\Delta} \Delta $	$\sum_{\Delta} 1$
Log	$ G $	$ G $	$\frac{ G }{ E }$	$ G $	$\frac{ G }{ E }$	$ G $	$\frac{ G }{ E }$	$ G $	$\frac{ G }{ E }$	$ G $	$\frac{ G }{ E }$
Copy	$ G ^2$	$ S $	1	$ S $	1	$ S G $	$ G $	$ S $	1	$ S G $	$ G $
Copy+Log	$\frac{ G ^2}{ E }$	$ S + E $	2	$ S + E $	2	$ G $	$\frac{ G }{ E }$	$ S + E $	2	$ G $	$\frac{ G }{ E }$
Node Centric	$2 G $	$2 \cdot G $	$ N $	$ C $	1	$ C $	1	$ R \cdot V $	$ R $	$ R \cdot V $	$ R $
DeltaGraph	$ G (h+1)$	$h \cdot S + E $	$2h$	$h \cdot S + E $	$2h$	$ G $	$\frac{ G }{ E }$	$h \cdot (S + E)$	$2h$	$ G $	$\frac{ G }{ E }$
TGI	$ G (2h+3)$	$h \cdot S + E $	$2h$	$\frac{h \cdot S }{p} + \frac{ E }{p}$	$2h$	$ V (1 + \frac{ S }{p})$	$ V + 1$	$\frac{h \cdot (S + E)}{p}$	$2h$	$ V (1 + \frac{ S }{p})$	$ V + 1$

Table 1: Comparison of access costs for different retrieval queries and index storage for various temporal indexes. $|G|$ = number of changes in the graph; $|S|$ = size of a snapshot; h = height and $|E|$ = eventlist size; $|V|$ = number of changes to a node; $|R|$ = numbers of neighbors of a node; p = number of partitions in TGI. The metrics used are, sum of delta cardinalities ($\sum_{\Delta} |\Delta|$) and number of deltas ($\sum_{\Delta} 1$).

5. The partitioned deltas are clustered by the delta key. The given order of delta-key along with the placement-key implies that all partitions of a delta are stored contiguously, which makes it efficient to scan and read all partitions belonging to a delta in a snapshot query. Also, if the order of *did* and *pid* is reversed, it makes fetching a partition across different deltas more efficient.

Implementation and Architecture: TGI uses Cassandra for its delta storage as well as metadata regarding partitioning, time-spans, etc. TGI consists of a *Query Manager* (QM) is responsible for planning, dividing and delegating the query to one or more *Query Processors* (QP). Multiple QPs query the datastore in parallel and process the raw deltas into the required result. Depending on the query specification, the distributed result is either aggregated at a particular QP (the QM) or returned to the client which made the request without aggregation. An *Index Manager* is responsible for the construction and maintenance activities of the index. We omit further details and refer the reader to the extended version [22].

4.5 Dynamic Graph Partitioning

Partitioning of the deltas is an essential aspect of TGI and provides cheaper access to subgraph elements when compared to DeltaGraph or similar indexes. The two traditional approaches to partitioning a static graph are random (node-id hash-based) or locality-based (min-cut, max-flow) partitioning. Random partitioning is simpler and involves minimal bookkeeping. However, since it loses locality, it is unsuitable for neighborhood-level granularity access. Locality-aware partitioning, on the other hand, preserves locality but incurs extra bookkeeping in form of a {node-id:partition-id} map. TGI is designed to work with either configuration as desired, as well as different partition size specifications. TGI also supports replication of edge-cuts for further speed up of 1-hop neighborhoods. It uses a separate *auxiliary delta partition* besides each delta partition to store the replication, thereby preventing extra read cost for snapshot or node centric queries. More details on this can be found in the extended manuscript.

Locality-aware partitioning, however, faces an additional challenge with time-evolving graphs. With the change in size and topology of a graph, a partitioning deemed good (with respect to locality) at an instant may cease to be good at a later time. A probable approach of frequent repartitioning over time would maintain partitioning quality, but leads to excessive amounts of bookkeeping, which in turn leads to degradation of performance while accessing different node or neighborhood versions.

Our approach of dealing with this dilemma is described as follows. For a time-evolving graph, $G(t)$, we update the partitioning once at the beginning of each *time span*. The partitioning valid during a time-span τ , is decided as the collectively best partitioning for the graph during time τ , G^τ . Now, the best-suited partition-

ing for a graph over a time-interval G^τ is performed by projecting it to a static graph using a function, $\Omega(G^\tau)$, followed by a static-graph partitioning. Ω could be defined in various ways, depending on the best-deemed interpretation of a representative static graph. Any definition, however, must retain all and only the nodes that appeared in G^τ . In TGI, the default choice of Ω is called *Union-Mean* and includes all edges that appeared in G^τ with the edge-weights computed as a function of time-fraction of existence. We refer the reader to the extended manuscript for further details on different choices of Ω , contrast of this technique with other alternatives, and comments on the associated problem of finding the appropriate boundaries of time-spans.

4.6 Fetching Graph Primitives

We briefly describe how the different types of retrieval queries are executed. The details of the algorithms can be found in the extended version of the paper.

Snapshot Retrieval: In snapshot retrieval, the state of a graph at a time point is retrieved. Given a time t_s , the query manager locates the appropriate time span T such that $t_s \in T$, within which, it figures out the path from the root of the TGI to the leaf closest to the given time point. All the snapshot deltas, $\Delta_{s1}, \Delta_{s2}, \dots, \Delta_{sm}$, (i.e., all the corresponding partitions) along that path from root to the leaf, and the eventlists from the leaf node to the time point, $\Delta_{e1}, \Delta_{e2}, \dots, \Delta_{en}$ are fetched and merged appropriately as: $\sum_{i=1}^m \Delta_{si} + \sum_{i=1}^n \Delta_{ei}$ (notice the order). This is performed across different query processors covering the entire set of horizontal partitions. This is conceptually similar to the DeltaGraph snapshot reconstruction with the addition of the aspect of partitions.

Node's history: Retrieving a node's history during time interval, $[t_s, t_e]$ involves finding the state of the graph at point t_s , and all changes during the time range (t_s, t_e) . The first one is done in a similar manner to snapshot retrieval except the fact that we look up only a specific delta partition in a specific horizontal partition, that the node belongs to. The second part happens through fetching the node's version chain to determine its points of changes during the given range. The respective eventlists are fetched and filtered for the given node.

k-hop neighborhood (static): In order to retrieve the k-hop neighborhood of a node, we can proceed in two possible ways. One of them is to fetch the whole graph snapshot and filter the required subgraph. The other is to fetch the given node, and then determine its neighbors, fetch them, and recurse. It is easy to see that the performance of the second method will deteriorate fast with growing k . However for lower values, typically $k \leq 2$, the latter is faster or at least as good, especially if we are using neighborhood replication as discussed in a previous subsection. In case of a neighborhood

fetch, the query manager automatically fetches the auxiliary portions of deltas (if they exist), and if the required nodes are found, further lookup is terminated.

Neighborhood evolution: Neighborhood evolution queries can be posed in two different ways. First, requesting all changes for a described neighborhood, in which case the query manager fetches the initial state of the neighborhood followed by the events indicating the change. Second, requesting the state of the neighborhood at multiple specific time points. This translates to the retrieval of multiple single neighborhoods fetch tasks.

5. ANALYTICS FRAMEWORK

In this section, we describe the *Temporal Graph Analysis Framework (TAF)*, that enables programmers to express complex analytical tasks on time-evolving graphs and execute them in a scalable, parallel, in-memory manner. We present details of the novel computational model, including a set of operators and operands. We also present the details of implementation on top of Apache Spark, as well as the user API (exposed through Python and Java). Finally, we describe TAF’s coordination with TGI, particularly the parallel data transfer protocol, that provides a complete ecosystem for historical graph management and analysis.

5.1 Data and Computational Model

At the heart of this analytics framework is an abstraction with the view of historical graph as a *set of nodes (or subgraphs) evolving over time*. The choice of temporal nodes as a primitive is instrumental in enabling us to express a wide range of fetch and compute operations in an intuitive manner. More significantly, it provides us with the appropriate basis for the parallelizing computation of arbitrary analysis tasks. The *temporal nodes* and *set of temporal nodes* bear a correspondence to *tuples* and *tables* of the relational algebra, as the basic unit of data and the prime operand, respectively. The two central data types are defined below:

DEFINITION 11 (TEMPORAL NODE). A *temporal node* ($NodeT$), N^T , is defined as a sequence of all and only the states of a node N over a time range, $T = [t_s, t_e)$. All the k states of the node must have a valid time duration T_i , such that $\cup_i^k T_i = T$ and $\cap_i^k T_i = \phi$.

DEFINITION 12 (SET OF TEMPORAL NODES). A *SoN*, is defined as a set of r temporal nodes $\{N_1^T, N_2^T \dots N_r^T\}$ over a time range, $T = [t_s, t_e)$, as depicted in Figure 4.

The *NodeT* class provides a range of methods to access the state of the node at various time points, including: `getVersions()` which returns the different versions of the node as a list of static nodes (*NodeS*), `getVersionAt()` which finds a specific version of the node given a timepoint, `getNeighborIDsAt()` which returns IDs of the neighbors at the specified time point, and so on.

A *Temporal Subgraph (SubgraphT)* generalizes *NodeT* and captures a sequence of the states of a subgraph (i.e., a set of nodes and edges among them) over a period of time. Typically the subgraphs correspond to k -hop neighborhoods around a set of nodes in the graph. An analogous `getVersionAt()` function can be used to retrieve the state of the subgraph as of a specific time point as an in-memory *Graph* object (the user program must ensure that any graph object so created can fit in the memory of a single machine). A *Set of Temporal Subgraphs (SoTS)* is defined analogously to *SoN* as a set of temporal subgraphs.

5.2 Temporal Graph Analysis Library

The important temporal graph algebra operators supported by our system are described below.

Figure 4: SoN: A set of nodes can be abstracted as a 3 dimensional array with temporal, node and attribute dimensions.

1. **Selection** accepts an SoN or an SoTS along with a boolean function on the nodes or the subgraphs, and returns an SoN or SoTS. It performs *entity-centric filtering* on the operand, and does not alter temporal or attribute dimensions of the data.
2. **Timeslicing** accepts an SoN or an SoTS along with a timepoint (or time interval) t , finds the state of each of individual nodes or subgraphs in the operand as of t , and returns it as another SoN or SoTS, respectively (SoN/SoTS can represent sets of static nodes or subgraphs as a well). The operator can accept a list of timepoints as input and return a list.
3. **Graph** accepts an SoN and returns an in-memory *Graph* object containing the nodes in the SoN (with only the edges whose both endpoints are in the SoN). An optional parameter, t_p , may be specified to get a *GraphS* valid at time t_p .
4. **NodeCompute** is analogous to a *map* operation; it takes as input an SoN (or an SoTS) and a function, and applies the function to all the individual nodes (subgraphs) and returns the results as a set.
5. **NodeComputeTemporal**. Unlike *NodeCompute*, this operator takes as input a function that operates on a static node (or subgraph) in addition to an SoN (or an SoTS); for each node (subgraph), it returns a sequence of outputs, one for each different state (version) of that node (or subgraph). Optionally, the user may specify another function (*NodeCompute-Delta*, described next) that operates on the delta between two versions of a node (subgraph). Another optional parameter is a method describing points of time at which computation needs to be performed; in the absence of it, the method will be evaluated at all the points of change.
6. **NodeComputeDelta** operator takes as input: (a) a function that operates on a static node (or subgraph) and produces an output quantity, (b) an SoN (or an SoTS), (c) a function that operates on the following: a static node (or subgraph), some auxiliary information pertaining to that state, and an *update* (event) to it. This operator returns a sequence of outputs, one for each state of the node (or subgraph), similar to *NodeComputeTemporal*. However, it computes the required quantity for each version incrementally instead of computing it afresh. An optional parameter is the method describing points of time at which to base the comparison. An optional parameter is a method describing points of time at which computation needs to be performed; in the absence of it, the method will be evaluated at all the points of change.
7. **Compare** operator takes as input two SoNs (or two SoTSs) and a scalar function (returning a single value), computes the function value over all the individual components, and returns the differences between the two as a set of (*node-id*, *difference*) pairs. This operator tries to abstract the common operation of

comparing two different snapshots of a graph at different time points. A simple variation of this operator takes a single SoN (or SoTS) and two timepoints as input, and does the compare on the timeslices of the SoN as of those two timepoints. An optional parameter is the method describing points of time at which to base the comparison.

8. **Evolution** operator samples a specified quantity (provided as a function) over time to return evolution of the quantity over a period of time. An optional parameter is the method describing points of time at which to base the evolution.
9. **TempAggregation** abstractly represents a collection of temporal aggregation operators such as Peak, Saturate, Max, Min, and Mean over a scalar timeseries. The aggregation operations are performed over a specified quantity for an SoN or SoTS. For instance, finding “times at which there was a *peak* in the network density” is used to find eventful timepoints of high interconnectivity such as conversations in a cellular network, or high transactional activity in a financial network.

5.3 System Implementation

The library is implemented in Python and Java and is built on top of the Spark API. The choice of Spark provides us with an efficient in-memory cluster compute execution platform, circumventing dealing with the issues of data partitioning, communication, synchronization, and fault tolerance. We provide a GraphX integration for utilizing the capabilities of the Spark based graph processing system for static graphs. Note that while we use Spark for implementation, the concepts presented as a part of the TAF are general and can be implemented over other distributed frameworks such as DryadLINQ⁶.

The key abstraction in Spark is that of an RDD, which represents a collection of objects of the same type, stored across a cluster. SoN and SoTS are implemented as RDDs of NodeT and SubgraphT respectively (i.e., as RDDTG<NodeT> and RDDTG<SubgraphT>, where RDDTG extends RDD class). Note that the in-memory graph objects may be implemented using any popular graph representation, specially the ones that support useful libraries on top. We now describe in brief the implementation details for NodeT and SubgraphT, followed by details of the incremental computational operator, and the parallel data fetch operation.

Figure 5 shows sample code snippets for three different analytical tasks – (a) finding the node with the *highest clustering coefficient* in a historical snapshot; (b) *comparing different communities* in a network; (c) finding the *evolution of network density* over a sample of ten points.

NodeT and SubgraphT: A set of temporal nodes is represented with an RDD of NodeT (temporal node). A temporal node contains the information for a node during a specified time interval. The question of the appropriate physical storage of the NodeT (or SubgraphT) structure is quite similar to storing a temporal graph on disk such as the one using a DeltaGraph or a TGI, however, in-memory instead of disk. Since NodeT is fetched at query time, it is preferable to avoid creating a complicated index, since the cost to create the index at query time is likely to offset any access latency benefits due to the index. Upon observing several analysis tasks, we noticed that the common access pattern is mostly in chronological order, i.e., the query requesting the subsequent versions or changes, in order of time. Hence, we store NodeT (and SubgraphT) as an initial snapshot of the node (or subgraph), followed by a list of chronologically sorted events. It provides methods such as GetStartTime(), GetEndTime(), GetStateAt(),

    '\24, 2008').fetch()
gm = GraphMetrics()
evol = son.GetGraph().Evolution(gm.density, 10)
print('Graph density over 10 points=%s'%evol)
```

(c) Evolution of network density

Figure 5: Examples of analytics using the TAF Python API.

GetIterator(), Iterator.GetNextVersion(), Iterator.GetNextEvent(), and so on. We omit their details as their functionality is apparent from the nomenclature.

NodeComputeDelta: NodeComputeDelta evaluates a quantity over each NodeT (or SubgraphT) using two supplied methods, $f()$ which computes the quantity on a state of the node or subgraph, and $f_{\Delta}()$, which updates the quantity on a state of the node or subgraph for a given set of event updates. Consider a simple example of computing the fraction of all nodes that contain a specific attribute value in a given SubgraphT. If this was performed using NodeComputeTemporal, the quantity will be computed afresh on each new version of the subgraph, which would cost $\mathcal{O}(N.T)$ operations where N is the size of the operand (number of nodes) and T is the number of versions. However, using incremental computation, each new version after the first snapshot can be processed in constant time, which adds up to $\mathcal{O}(N+T)$. While performing incremental computation, the corresponding $f_{\Delta}()$ method is expected to be defined so as to evaluate the nature of the event – whether it brings about any change in the output quantity or not, i.e., a scalar change value based upon the actual event and the concerned portions of the state of the graph, and also update the auxiliary structure, if used. Code snippet in Figure 6 illustrates the usage of NodeComputeTemporal and NodeComputeDelta in a similar example.

Consider a somewhat more intricate example, where one needs to find counts of a small pattern *over time* on an SoTS, such as finding the occurrence of a subgraph pattern in the data graph’s history. In order to perform such pattern matching over long sequences of subgraph versions, it is essential to maintain certain inverted indexes which can be looked up to answer in constant time whether an event has caused a change in the answer from a previous state or caused a change in the index itself, or both. Such inverted indexes, quite common to subgraph pattern matching, are required to be updated with every event; otherwise, with every new event update, we would need to look up the new state of the subgraph afresh which would simply reduce it to performing non-indexed subgraph pattern matching over new snapshots of a subgraph at each time point, which is a fairly expensive task. In order to utilize a constantly updated set of indices, the auxiliary information, which is a parameter and a return type for $f_{\Delta}()$, can be utilized. Note that such an incremental computational operator opens up possibilities of utiliz-

```

tgiH = TGIHandler(tgiconf, "dblp", sparkcontext)
sots = SOTS(k=2, tgiH).Timeslice('t >= Nov 1,2009 and t < Nov 30,\'
    '2009').fetch()
labelCount = sots.NodeComputeTemporal(fCountLabel)
labelCount = sots.NodeComputeDelta(fCountLabel, fCountLabelDel)

def fCountLabel(g):
    labCount = 0
    for node in g.GetNodes():
        if node.GetPropValue('EntityType') == 'Author':
            labCount += 1
    return labCount

def fCountLabelDel(gPrev, valPrev, event):
    valNew = valPrev
    if event.Type == EType.AttribValAlter:
        if event.AttribKey == 'EntityType':
            if event.PrevVal == 'Author':
                valNew = valPrev - 1
            else if event.NextVal == 'Author':
                valNew = valPrev + 1
    return valNew

```

Figure 6: Incremental computation using different options: NodeComputeTemporal and NodeComputeDelta to compute counts of nodes with a specific label in subgraphs over time.

ing a large body of algorithmic work in online and streaming graph query evaluation for the purpose of graph analytics.

Specifying interesting time points: In the map-oriented version operators on an SoN or an SOTS, the time points of evaluation, by default, are all the points of change in the given operand. However, a user may choose to provide a definition of which points to select. This can be as simple as returning a constant set of time-points, or based on a more complex function of the operand(s). Except the Compare operator, which accepts two operands, other operators allow an optional function, which works on a single temporal operand; the compare accepts a similar function that operates on two such operands. Two such examples can be seen in Figure 7.

```

tgiH = TGIHandler(tgiconf, "wiki", sparkcontext)
son = SON(tgiH).Select("id < 5000").Timeslice("t >= oct"
    "\"24, 2008").fetch()
gm = GraphMetrics()
evol = son.GetGraph().Evolution(gm.density,
    \ selectTimepointsMinimal)
print('Graph density over 3 points=%s'%evol)

def selectTimepointsMinimal(son):
    time_arr = []
    st = son.GetStartTime()
    et = son.GetEndTime()
    time_arr.append(st)
    time_arr.append((st + et)/2)
    time_arr.append(et)
    return time_arr

```

Figure 7: Using the optional timepoint specification function for an Evolution query with the start, middle and endpoint of SON.

Data Fetch: In a temporal graph analysis task, we first need to instantiate a *TGI connection handler* instance. It contains configurations such as address and port of the TGI query manager host, graph-id, and a SparkContext object. Then, a SON (or SOTS) object is instantiated by passing the reference to the TGI handler, and any query specific parameters (such as k-value for fetching 1-hop neighborhoods with SOTS). The next few instructions specify the semantics of the graph to be fetched from the TGI. This is done through the commands explained in Section 5.1, such as the Select, Filter, Timeslice, etc. However, the actual retrieval from the index doesn't happen until the first statement following the specification instructions. A fetch() command can be used explicitly to tell the system to perform the fetch operation. Upon the fetch() call, the analytics framework sends the combined instructions to the query planner of the TGI, which translates those instructions into an optimal retrieval plan. This prevents the system from retrieving large amounts of data from the index that is a superset of the required information and prune it later.

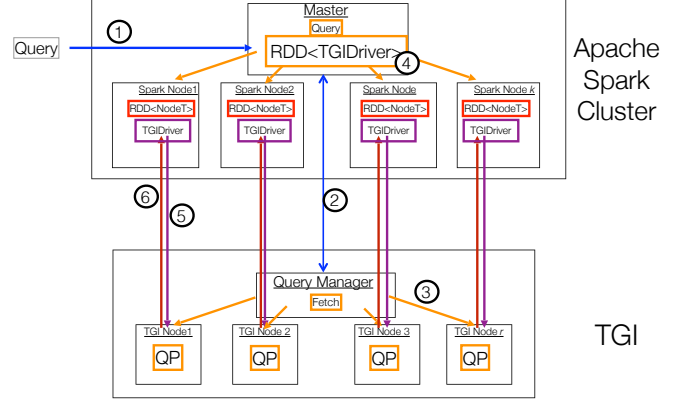

Figure 8: A flow diagram of the parallel fetch operation between the TGI and TAF clusters. The numbers in circles indicate the relative order of events and arrowheads indicate the direction of flow.

The analytics engine runs in parallel on a set of machines, so does the graph index. The parallelism at both places speeds up and scales both the tasks. However, if the retrieval graph at the TGI cluster was aggregated at the Query Manager and sent serially to the master of the analytical framework engine after which it was distributed to the different machines on the cluster, it would create a space and time bottleneck at the Query Manager and the master, respectively, for large graphs. In order to bypass this situation, we have designed a parallel fetch operation, in which there is a direct communication between the nodes of the analytics framework cluster and the nodes of the TGI cluster. This happens through a protocol that can be seen in Figure 8 and summarized below:

1. Analytics query containing fetch instructions is received by the TAF master.
2. A handshake between the TAF master and TGI query manager is established. The latter receives fetch instructions and the former is made aware of the active TGI query processors.
3. Parallel fetch starts at the TGI cluster.
4. The TAF master instantiates a TGIDriver instance at each of its cluster machines wrapped in a RDD.
5. Each node at the TAF performs a handshake with one or more of the TGI nodes.
6. Upon completion of fetch at TGI, the individual TGI nodes transfer the SoN to an RDDs on the corresponding TAF nodes.

More details on the TGI-TAF integration can be found in the longer version of the paper [22].

6. EXPERIMENTAL EVALUATION

In this section, we empirically evaluate the efficiency of TGI and TAF. To recap, TGI is a persistent store for entire histories of large graphs, that enables fast retrieval for a diverse set of graph primitives – snapshots, subgraphs, and nodes at past time points or across intervals of time. We primarily highlight the performance of TGI across the entire spectrum of retrieval primitives. We are not aware of a baseline that may compete with TGI across all or a substantial subset of these retrieval primitives. Specialized alternatives such as DeltaGraph for snapshot retrieval is highly unsuitable for node or neighbor version retrieval; a version centric index may be specialized for node-version retrieval but is highly unsuitable for snapshot

Figure 9: Snapshot retrieval times for varying parallel fetch factor (c), on Dataset 1; $m = 4$; $r = 1$, $ps = 500$.

or neighborhood-version style retrieval. Also note that TGI generalizes all the known approaches including those two; using appropriate parameter configurations, it can even converge to any specific alternative. Secondly, we demonstrate the scalability of TGI design through experiments on parallel fetching for large and varying data sizes. Finally, we also report experiments demonstrating computational scalability of the TAF for a graph analysis task, as well as the benefits of our incremental computational operator.

Datasets and Notation: We use four datasets: (1) Wikipedia citation network consisting of 266,769,613 edge addition or modification events from Jan 2001 to Sept 2010. At its largest point, the graph consists of 21,443,529 nodes and 122,075,026 edges; (2) We augment Dataset 1 by adding around 333 million synthetic events which randomly add new edges or delete existing edges over a period of time, making a total of 700 million events; (3) Similarly, we add 733 million events, making the total around 1 billion events; (4) Using a Friendster gaming network snapshot, we add synthetic dates at uniform intervals to 500 million events with a total of approximately 37.5 million nodes and 500 million edges.

Following key parameters that are varied in the experiments: data store machine count (m), replication across dataset (r), number of parallel fetching clients (c), eventlist size (l), snapshot or eventlist partition size (ps), and Spark cluster size (m_a).

We conducted all experiments on an Amazon EC2 cluster. Cassandra ran on machines containing 4 cores and 15GB of available memory. We did not use row caching and the actual memory consumption was much lower than the available limit on those machines. Each fetch client ran on a single core with up to 7.5GB available memory. The machines with TAF nodes running Spark workers ran on a single core and 7.5GB of available memory each.

Snapshot retrieval: Figure 9 shows the snapshot retrieval times for Dataset 1 for different values of the parallel fetch factor, c . We observe that the retrieval cost is directly proportional to the size of the output. Further, using multiple clients to retrieve the snapshots in parallel gives near-linear speedup, especially with low parallelism. This demonstrates that TGI can exploit available parallelism well. We expect that with higher values of m (i.e., if the index were distributed across a more machines), linear speedup would be seen for larger values of c (this is corroborated by the next set of experiments). Figure 11c shows snapshot retrieval times for Dataset 4.

Figure 10 shows snapshot retrieval performance for three different sets of values for m and r . We can see that while there is no considerable difference in performance across the different configurations, using two storage machines slightly decreases the query latency over using one machine, in the case of a single query client, $c = 1$. For higher c values, we see that $m = 2$ has a slight edge over $m = 1$. Also, the behavior for the two $m = 1$ and $m = 2$; $r = 2$ cases are quite similar for same c values. However, we observed that the

latter case allows a higher possibility of c value whereas the former peaks out at a lower c value. Further, compression for deltas is negligible for TGI. We omit the detailed points of our investigation, but Figure 11a is representative of the general behavior.

In the special case of $ps \rightarrow \infty$, TGI becomes structurally equivalent to a DeltaGraph. While DeltaGraph provides the most efficient way of performing snapshot retrieval, we show that using lower values of ps in TGI only has a marginal impact on the performance of snapshot retrieval (Figure 11b). This occurs due to the TGI design policy of storing all the partitions of a delta contiguously in a cluster and avoiding any additional seek costs. Hence, DeltaGraph is subsumed as a part of TGI and we omit further comparisons in this respect. Also note that the internals of snapshot retrieval through DeltaGraph have been thoroughly explored in our prior work [21].

Node History Retrieval: Smaller eventlists or partition sizes provide a lower latency time for retrieving different versions of a node, which can be seen in Figure 12a and Figure 12c, respectively. This is primarily due to the reduction in effort for fetching and deserialization. A higher parallel fetch factor is effective in reducing the latency for version retrieval (Figure 12b). Note that the performances of version and snapshot retrieval for varying partition sizes are opposite. However, smaller eventlist sizes benefit both version and snapshot retrieval. Node version retrieval for Dataset 4 shows a similar behavior, which can be seen in Figure 14.

Neighborhood Retrieval: We compared the performance of retrieving 1-hop neighborhoods, both static and specific versions, using different graph partitioning and replication choices. A topological, flow-based partitioning accesses fewer graph partitions compared to a random partitioning scheme, and a 1-hop neighborhood replication restricts the access to a single partition. This can be seen in Figure 13a for 1-hop neighborhood retrieval latencies. As discussed in Section 4, the 1-hop replication does not affect other queries involving snapshots or individual nodes, as the replicated portion is stored separately from the original partition. In case of a 2-hop neighborhood retrieval, there are similar performance benefits over random partitioning.

Increasing Data Over Time: We observed the fetch performance of TGI with an increasing size of the index. We measured the latencies for retrieving certain snapshots upon varying the time duration of the graph dataset, as shown in Figure 13b. Datasets 2 and 3 contain additional 333 million and 733 million events over dataset 1, respectively. Only a marginal difference in snapshot retrieval performance demonstrates TGI’s scalability for large datasets.

Conducting Scalable Analytics: We examined TAF’s performance through an analytical task for determining the highest local clustering coefficient in historical graph snapshot. Figure 13c shows compute times for the given task on different graph sizes, as well as varying size of the Spark cluster. Speedups due to parallel execution can be observed, especially for larger datasets.

Temporal Computation: Earlier in the chapter, we presented two separate ways of computing a quantity over changing versions of a graph (or node). Those include, evaluating the quantity on different versions of the graph separately, and alternatively, performing it in an incremental fashion, utilizing the result for the previous version and updating it with respect to the graph updates. This can be seen for a simple node label counting task in Figure 6. the benefits due to the incremental (NodeComputeDelta operator) computation over a version-based computation (NodeComputeTemporal operator) can be seen in Figure 15.

Figure 10: Snapshot retrieval times across different m and r values on Dataset 1.

7. CONCLUSION

Graph analytics are increasingly considered crucial in obtaining insights about how interconnected entities behave, how information spreads, what are the most influential entities in the data, and many other characteristics. Analyzing the history of a graph's evolution can provide significant additional insights, especially about the future. Most real-world networks however, are large and highly dynamic. This leads to creation of very large histories, making it challenging to store, query, or analyze them. In this paper, we presented a novel Temporal Graph Index that enables compact storage of very large historical graph traces in a distributed fashion, supporting a wide range of retrieval queries to access and analyze only the required portions of the history. Our experiments demonstrate its efficient retrieval performance across a wide range of queries, and can effectively exploit parallelism in a distributed setting. We also presented a distributed analytics framework, built on top of Apache Spark, that allows analysts to quickly write complex temporal analysis tasks and execute them scalably over a cluster.

ABSTRACT

There is considerable interest in the design and development of distributed systems that can execute algorithms to process large graphs. Serializability guarantees that parallel executions of a graph algorithm produce the same results as some serial execution of that algorithm. Serializability is required by many graph algorithms for accuracy, correctness, or termination but existing graph processing systems either do not provide serializability or cannot provide it efficiently. To address this deficiency, we provide a complete solution that can be implemented on top of existing graph processing systems. Our solution formalizes the notion of serializability and the conditions under which it can be provided for graph processing systems. We propose a novel partition-based synchronization approach that enforces these conditions to efficiently provide serializability. We implement our partition-based technique into the open source graph processing system Giraph and demonstrate that our technique is configurable, transparent to algorithm developers, and provides large across-the-board performance gains of up to $26\times$ over existing techniques.

1. INTRODUCTION

Graph data processing has become ubiquitous due to the large quantities of data collected and processed to solve real-world problems. For example, Facebook processes massive social graphs to compute popularity and personalized rankings, find communities, and propagate advertisements for over 1 billion monthly active users [16]. Google processes web graphs containing over 60 trillion indexed webpages to determine influential vertices [19].

Graph processing solves real-world problems through algorithms that are implemented and executed on *graph processing systems*. These systems provide programming and computation models for graph algorithms as well as correctness guarantees that algorithms require.

One key correctness guarantee is *serializability*. Informally, a graph processing system provides serializability if it

can guarantee that parallel executions of an algorithm, implemented with its programming and computation models, produce the same results as some serial execution of that algorithm [18].

Serializability is required by many algorithms, for example in machine learning, to provide both theoretical and empirical guarantees for convergence or termination. Parallel algorithms for combinatorial optimization problems experience a drop in performance and accuracy when parallelism is increased without consideration for serializability. For example, the Shotgun algorithm for L_1 -regularized loss minimization parallelizes sequential coordinate descent to handle problems with high dimensionality or large sample sizes [11]. As the number of parallel updates is increased, convergence is achieved in fewer iterations. However, after a sufficient degree of parallelism, divergence occurs and *more* iterations are required to reach convergence [11]. Similarly, for energy minimization on NK energy functions (which model a system of discrete spins), local search techniques experience an abrupt degradation in the solution quality as the number of parallel updates is increased [32]. Some algorithms also require serializability to prevent unstable accuracy [27] while others require it for statistical correctness [17]. Graph coloring requires serializability to terminate on dense graphs [18] and, even for sparse graphs, will use significantly fewer colors and complete in only a single iteration (rather than many iterations) when executed serializably.

Providing serializability in a graph processing system is fundamentally a system-level problem that informally requires: (1) vertices see up-to-date data from their neighbors and (2) no two neighboring vertices execute concurrently. The general approach is to pair an existing system or computation model with a *synchronization technique* that enforces conditions (1) and (2). Despite this, of the graph processing systems that have appeared over the past few years, few provide serializability as a configurable option. For example, popular systems like Pregel [28], Giraph [1], and GPS [31] pair a vertex-centric programming model with the bulk synchronous parallel (BSP) computation model [34] but do not provide serializability.

Giraphx [33] provides serializability by pairing the asynchronous parallel (AP) model, which is an asynchronous extension of the BSP model, with the single-layer token passing and vertex-based distributed locking synchronization techniques. However, it implements these synchronization techniques as part of specific user algorithms rather than within the system, meaning algorithm developers must re-implement the techniques into every algorithm that they

Figure 1: Spectrum of synchronization techniques.

write. Consequently, Giraphx unnecessarily couples and exposes internal system details to user algorithms, meaning serializability is neither a configurable option nor transparent to the algorithm developer. Furthermore, its implementation of vertex-based distributed locking unnecessarily divides each superstep, an iteration of computation, into multiple sub-supersteps in which only a subset of vertices can execute. This exacerbates the already expensive communication and synchronization overheads associated with the global synchronization barriers that occur at the end of each superstep [20], resulting in poor performance.

GraphLab [27], which now subsumes PowerGraph [18], takes a different approach by starting with an asynchronous implementation of the Gather, Apply, Scatter (GAS) computation model. This asynchronous mode (GraphLab async) avoids global barriers by using distributed locking. GraphLab async provides the option to execute with or without serializability and uses vertex-based distributed locking as its synchronization technique. However, GraphLab async suffers from high communication overheads [22, 20] and scales poorly with this technique. Moreover, neither GraphLab nor Giraphx provide a theoretical framework for proving the correctness of their synchronization techniques.

Irrespective of the specific system, synchronization techniques used to enforce conditions (1) and (2) fall on a spectrum that trades off parallelism with communication overheads (Figure 1). In particular, single-layer token passing and vertex-based distributed locking fall on the extremes of this spectrum: token passing uses minimal communication but unnecessarily restricts parallelism, forcing only one machine to execute at a time, while vertex-based distributed locking uses a dining philosopher algorithm to maximize parallelism but incurs substantial communication overheads due to every vertex needing to synchronize with their neighbors.

To overcome these issues, we first formalize the notion of serializability in graph processing systems and establish the conditions under which it can be provided. To the best of our knowledge, no existing work has presented such a formalization. To address the shortcomings of the existing techniques, we introduce a fundamental design shift towards *partition aware* synchronization techniques, which exploit graph partitions to improve performance. In particular, we propose a novel *partition-based distributed locking* solution that allows control over the coarseness of locking and the resulting trade-off between parallelism and communication overheads (Figure 1). We implement all techniques at the system level in the open source graph processing system Giraph so that they are performant, configurable, and transparent to algorithm developers. We demonstrate through experimental evaluation that our partition-based solution substantially outperforms existing techniques.

Our **contributions** are hence threefold: (i) we formalize the notion of serializability in graph processing systems and establish the conditions that guarantee it; (ii) we intro-

duce the notion of partition aware techniques and our novel partition-based distributed locking technique that enables control over the trade-off between parallelism and communication overheads; and (iii) we implement and experimentally compare the techniques with Giraph and GraphLab to show that our partition-based technique provides substantial across-the-board performance gains of up to $26\times$ over existing synchronization techniques.

This paper is organized as follows. In Section 2, we provide background on the BSP, AP, and GAS models. In Section 3, we formalize serializability and, in Sections 4 and 5, describe both existing techniques and our partition-based approach. In Section 6, we detail their implementations in Giraph. We present an extensive experimental evaluation of these techniques in Section 7 and describe related work in Section 8 before concluding in Section 9.

2. BACKGROUND AND MOTIVATION

In this section, we introduce the computation models and give a concrete motivation for serializability.

2.1 BSP Model

Bulk synchronous parallel (BSP) [34] is a computation model in which computations are divided into a series of (BSP) *supersteps* separated by global barriers. Pregel (and Giraph) pairs BSP with a vertex-centric programming model, where vertices are the units of computation and edges act as communication channels.

Graph computations are specified by a user-defined compute function that executes, in parallel, on all vertices in each superstep. The function specifies how each vertex processes its received messages, updates its vertex value, and who to send messages to. Importantly, messages sent in one superstep can be consumed/processed by their recipients only in the next superstep. Vertices can vote to halt to become inactive but are reactivated by incoming messages. The computation terminates when all vertices are inactive and no more messages are in transit.

Pregel and Giraph use a master/workers configuration. The master machine partitions the input graph across worker machines, coordinates all global barriers, and performs termination checks based on the two aforementioned conditions. The graph is partitioned by *edge-cuts*: each vertex belongs to a single worker while an edge can span two workers. Finally, BSP is *push-based*: messages are pushed by the sender and buffered at the receiver.

As a running example, consider the greedy graph coloring algorithm. Each vertex starts with the same color (denoted by its vertex value) and, in each superstep, selects the smallest non-conflicting color based on its received messages, broadcasts this change to its neighbors, and votes to halt. The algorithm terminates when there are no more color conflicts. Consider an undirected graph of four vertices partitioned across two worker machines (Figure 2). All vertices broadcast the initial color 0 in superstep 1 but the messages are not visible until superstep 2. Consequently, in superstep 2, all vertices update their colors to 1 based on stale data. Similarly for superstep 3. Hence, vertices collectively oscillate between 0 and 1 and the algorithm never terminates. However, if we could ensure that only v_0 and v_3 execute in superstep 2 and only v_2 and v_1 execute in superstep 3, then this problem would be avoided. As we will show in Section 4.3, serializability provides precisely this solution.

Figure 2: BSP execution of greedy graph coloring. Each graph is the state at the end of that superstep.

2.2 AP Model

The asynchronous parallel (AP) model improves on the BSP model by reducing staleness: instead of delaying all messages until the next superstep, vertices can immediately process any received messages (including ones sent in the same superstep). The AP model retains global barriers to separate supersteps, so messages that arrive too late to be seen by a vertex in superstep i (because the vertex was already executed) will be processed in the next superstep $i+1$. We use a more efficient and performant version of the AP model, described in [20], and its implementation in Giraph, which we will refer to as Giraph async.

Like BSP, the AP model can also fail to terminate for the greedy graph coloring algorithm. Consider again the undirected graph (Figure 3) and suppose that workers W_1 and W_2 execute their vertices sequentially as v_0 then v_2 and v_1 then v_3 , respectively. Furthermore, suppose the pairs v_0, v_1 and v_2, v_3 are each executed in parallel. Then the algorithm fails to terminate. Specifically, in superstep 1, v_0 and v_1 initialize their colors to 0 and broadcast to their neighbors. Due to the asynchronous nature of AP, v_2 and v_3 are able to see this message 0 and select the color 1. Similarly, in superstep 2, v_0 and v_1 now see each other's message 0 (sent in superstep 1) and also the message 1 from v_2 and v_3 , respectively, so they update their colors to 2. Similarly for v_2 and v_3 , who now update their colors to 0. Ultimately, the graph's state at superstep 4 returns to that at superstep 1, so the vertices are collectively cycling through three graph states in an infinite loop.

However, if we can force v_0 to execute concurrently with v_3 instead of v_1 (and v_2 with v_1), then neighboring vertices will not simultaneously pick the same color. Furthermore, if we ensure that v_2 and v_1 wait for the messages from v_3 and v_0 to arrive before they execute, then they will have up-to-date information on all their neighbors' colors. With these two constraints, graph coloring will terminate in just two supersteps. In Section 3, we present a theoretical framework for serializability that formalizes and incorporates these constraints as correctness criteria.

2.3 GAS Model

The Gather, Apply, and Scatter (GAS) model is used by GraphLab for both its synchronous and asynchronous modes, which we refer to as GraphLab sync and GraphLab async. These two system modes use the sync GAS and async GAS models, respectively. In GAS, each vertex pulls information from its neighbors in the gather phase, applies the accumulated data in the apply phase, and updates and activates neighboring vertices in the scatter phase.

Like Pregel and Giraph, GraphLab pairs GAS with a vertex-centric programming model. However, as evidenced by the Gather phase, GAS is *pull-based* rather than push-

Figure 3: AP execution of greedy graph coloring. Each graph is the state at the end of that superstep.

based. Furthermore, GraphLab partitions graphs by *vertex-cut*: for each vertex u , one worker owns the *primary copy* of u while all other workers owning a neighbor of u get a local read-only replica of u .

Sync GAS is similar to BSP: vertices are executed in supersteps separated by global barriers and the effects of apply and scatter of one superstep are visible only to the gather of the next superstep. Async GAS, however, is different from AP as it has no notion of supersteps. To execute a vertex u , each GAS phase individually acquires a write lock on u and read locks on u 's neighbors to prevent data races [3]. However, this does not provide serializability because GAS phases of different vertex computations can interleave [18]. To provide serializability, a synchronization technique must be added on top of async GAS. This technique prevents neighboring computations from interleaving by performing distributed locking over all three GAS phases.

Async GAS can similarly fail to terminate for graph coloring [18]. For example, for the graph in Figure 3, suppose both W_1 and W_2 each have two threads for their two vertices and that all four threads execute in parallel. Then, as described above, the GAS phases of different vertices will interleave, which causes vertices to see stale colors and so the execution is not guaranteed to terminate: it can become stuck in an infinite loop. In contrast, executing in async GAS with serializability will always terminate successfully.

3. SERIALIZABILITY

In this section, we present a theoretical framework that formalizes key conditions under which serializability can be provided for graph processing systems. Later, we show how serializability can be enforced efficiently in these systems.

3.1 Preliminaries

Since popular graph processing systems use a vertex-centric programming model, where developers specify the actions of a single vertex, we focus on vertex-centric systems. The formalisms that we will establish apply to all vertex-centric systems, irrespective of the computation models they use.

Existing work [18, 33] considers serializability for vertex-centric algorithms where vertices communicate only with their direct neighbors, which is the behaviour of the majority of algorithms that require serializability. For example, the GAS model supports only algorithms where vertices communicate with their direct neighbors [27, 18]. Thus, we focus on this type of vertex-centric algorithms. Our goal is to provide serializability transparently within the graph processing system, independent of the particular algorithm being executed.

In vertex-centric graph processing systems, there are two levels of parallelism: (1) between multiple threads within a single worker machine and (2) between the multiple worker

machines. Due to the distributed nature of computation, the input graph must be partitioned across the workers and so data replication will occur. To better understand this, let *neighbors* refer to both in-edge and out-edge neighbors.

DEFINITION 1. A vertex u is a machine boundary vertex, or m-boundary for short, if at least one of its neighbors v belongs to a different worker machine from u . Otherwise, u is a machine internal, or m-internal, vertex.

DEFINITION 2. A replica is local if it belongs to the same worker machine as its primary copy and remote otherwise.

Systems keep a read-only replica of each vertex on its owner’s machine and of each m-boundary vertex u on each of u ’s out-edge neighbor’s worker machines. This is a standard design used, for example, in Pregel, Giraph, and GraphLab. Remote replicas (of m-boundary vertices) exist due to graph partitioning: for vertex-cut partitioning, u ’s vertex value is explicitly replicated on every out-edge neighbor v ’s worker machine; for edge-cut, u is implicitly replicated because the message it sends to v , which is a function of u ’s vertex value, is buffered in the message store of v ’s machine. This distinction is unimportant for our formalism as we care only about whether replication occurs. Local replicas occur in push-based systems because message stores also buffer messages sent between vertices belonging to the same worker. In pull-based systems, local replicas are required for implementing synchronous computation models like sync GAS. For asynchronous models, pull-based systems may not always have local replicas (such as in GraphLab async) but we will consider the more general case in which they do (if they do not, then reads of such vertices will always trivially see up-to-date data).

DEFINITION 3. A read of a replica is fresh if the replica is up-to-date with its primary copy and stale otherwise.

An execution is *serializable* if it produces the same result as a serial execution in which all reads are fresh. Formally, this is one-copy serializability (1SR) [5]. Informally, we will say a system provides serializability if all executions conform to 1SR. In terms of traditional transaction terminology, we define a site as a worker machine, an item as a vertex, and a transaction as the execution of a single vertex. We detail such transactions next.

3.2 Transactions

We define a transaction to be the single execution of an arbitrary vertex u , consisting of a read on u and the replicas of u ’s in-edge neighbors followed by a write to u . The read acts only on u and its in-edge neighbors because u receives messages (or pulls data) from only its in-edge neighbors—it has no dependency on its out-edge neighbors. Denoting the read set as $N_u = \{u, u\text{’s in-edge neighbors}\}$, any execution of u is the transaction $T_i = r_i[N_u]w_i[u]$, or simply $T_i(N_u)$ as all transactions are of the same form.

Any $v \in N_u$ with $v \neq u$ is also annotated to distinguish it from the other read-only replicas of v . For example, if u belongs to worker A , we annotate the read-only replica as $v_A \in N_u$. However, the next two sections will show how we can drop these annotations.

Our definition relies only on the fact that the system is vertex-centric and not on the nuances of specific computation models. For example, although BSP and AP have

a notion of supersteps, the i for a transaction $T_i(N_u)$ has no relation to the superstep count. The execution of u in two different supersteps is represented by two different transactions $T_i(N_u)$ and $T_j(N_u)$. Our definitions also work when there is no notion of supersteps, such as in async GAS, or when there are per-worker logical supersteps (supersteps that are not globally coordinated), such as proposed in [20]. Thus, the notion of a transaction that follows from our above definition is consistent with the standard notion of a transaction [5]: it captures, for graph processing, the atomic unit of operation that acts on shared data (the graph state).

3.3 Our Approach

In contrast to traditional database systems, graph processing systems present unique constraints that need to be taken into account for providing serializability.

First, Pregel-like graph processing systems such as Giraph and GraphLab do not natively support transactions: they are not database systems and thus have no notion of commits or aborts. The naive solution is to implement transaction support into all graph processing systems. However, this requires a fundamental redesign of each system, which is neither general nor reusable. Moreover, such a solution fails to be modular: it introduces performance penalties for graph algorithms that do not require serializability.

Second, an abort in a graph processing system can result in prohibitively expensive (and possibly cascading) rollbacks on the distributed graph state: a transaction often involves sending messages to vertices of different worker machines, the effects of which are difficult to undo. Consequently, solutions relying on optimistic currency control are a poor fit for graph processing due to the high cost of aborts.

However, for graph processing systems, a *write-all* approach [5] can be used to keep replicas up-to-date because graph processing systems replicate only for distributed computation and not for availability. When a worker machine fails, we lose a portion of the input graph and so cannot proceed with the computation. Indeed, failure recovery requires all machines to rollback to a previous checkpoint [1, 27, 28], meaning the problem of pending writes to failed machines never occurs. In contrast, a write-all approach is very expensive for traditional database systems because they replicate primarily for better performance and/or availability.

Furthermore, as detailed in Section 3.2, the read and write sets of each transaction are known a priori (N_v and v , respectively, for a transaction $T_i(N_v)$), which means pessimistic concurrency control can be used to avoid costly aborts.

Our approach, at a high level, is to pair graph processing systems with a *synchronization technique*, which uses (1) a write-all approach to avoid data staleness and (2) pessimistic concurrency control to prevent conflicting transactions from starting. For the graph processing systems, (1) means vertices will always read from fresh replicas and so the system need not reason about versioning, while (2) means all transactions that start will commit, so aborts never occur and hence the system can treat all operations as final without needing explicit support for commits and aborts. Furthermore, this solution enables us to use transactions to formally reason about correctness without the burden of fundamentally redesigning each system to support transactions. Since aborts cannot occur, we also avoid the expensive penalties of distributed cascading rollbacks.

Using the definitions introduced in Section 3.2, we can

formalize our requirements into the following two conditions:

CONDITION C1. *Before any transaction $T_i(N_u)$ executes, all replicas $v \in N_u$ are up-to-date.*

CONDITION C2. *No transaction $T_i(N_u)$ is concurrent with any transaction $T_j(N_v)$ for all copies of $v \in N_u$, $v \neq u$.*

Next, we will prove that 1SR can be provided by enforcing these two conditions.

3.4 Correctness

We first prove, in Lemma 1, that enforcing condition C1 simplifies the problem of providing 1SR to that of providing standard serializability on a single logical copy of each vertex (i.e., without data replication).

LEMMA 1. *If condition C1 is true, then it suffices to use standard serializability theory where operations are performed on a single logical copy of each vertex.*

PROOF. Condition C1 ensures that before every transaction $T_i(N_u)$ executes, the replicas $v \in N_u$ are all up-to-date. Then all reads $r_i[N_u]$ see up-to-date replicas and are thus the same as reading from the primary copy of each $v \in N_u$. Hence, there is effectively only a single logical copy of each vertex, so we can apply standard serializability theory. \square

Theorem 1 then establishes the relationship between 1SR and conditions C1 and C2.

THEOREM 1. *All executions are serializable for all input graphs if and only if conditions C1 and C2 are both true.*

PROOF SKETCH. Due to space constraints, we will briefly sketch only the key ideas of the proof. The full proof is provided in [21].

(If) Since condition C1 is true, by Lemma 1 we can apply standard serializability theory [5]. It can then be shown that, for all input graphs, if condition C2 is true then it is impossible for the read and write sets of two arbitrary transactions to overlap. Thus, transactions never conflict and so the serialization graph [5] is always acyclic.

(ONLY IF) We prove the inverse (if either condition is false then there exists a non-serializable execution for some input graph) by considering an input graph with two vertices connected by an undirected edge. When C1 is true and C2 is false, we can construct a non-serializable history with two parallel but conflicting transactions. When C2 is true and C1 is false, replicas are no longer kept up-to-date and so, by placing each vertex on a different worker, we can construct a serial history that violates 1SR. \square

3.5 Enforcing Serializability

The computation models from Section 2 do not enforce conditions C1 and C2 and therefore, by Theorem 1, do not provide serializability. Consequently, graph processing systems that implement these models also do not provide serializability. Moreover, these models do not guarantee fresh reads even under serial executions (on a single machine or under the sequential execution of multiple machines). For example, BSP effectively updates replicas lazily¹ because messages sent in one superstep, even if received, cannot be

¹The “synchronous” in BSP refers to the global communication barriers, *not* the method of replica synchronization.

read by the recipient in the same superstep. Thus, both m-boundary and m-internal vertices (Definition 1) suffer stale reads under a serial execution. While AP reduces this staleness and can update local replicas eagerly, it propagates messages to remote replicas lazily without the guarantees of condition C1 and so stale reads can again occur under a serial execution of multiple machines.

As mentioned in Section 3.3, to provide serializability, we enforce conditions C1 and C2 by adding a synchronization technique (Sections 4 and 5) to the systems that implement the above computation models. These synchronization techniques implement a write-all approach for updating replicas, which is required for enforcing condition C1. They also ensure that a vertex u does not execute concurrently with any of its in-edge and out-edge neighbors. At first glance, this appears to be stronger than what condition C2 requires. However, suppose v is an out-edge neighbor of u and v is currently executing. Then if u does not synchronize with its out-edge neighbors, it will erroneously execute concurrently with v , violating condition C2 for v . Alternatively, if v is an out-edge neighbor of u then u is an in-edge neighbor of v , so they must not execute concurrently.

4. EXISTING SYNCHRONIZATION TECHNIQUES

Token passing and distributed locking are the two general approaches for implementing synchronization techniques that enforce conditions C1 and C2. In this section, we review two existing synchronization techniques: single-layer token passing and vertex-based distributed locking.

4.1 Preliminaries

How a synchronization technique implements a write-all approach (Section 3.3) depends on whether the computation model is synchronous or asynchronous.

In asynchronous computation models (AP and async GAS), replicas immediately apply received updates. Thus, local replicas can be updated eagerly, since there is no network communication (Section 6). Remote replicas, however, are updated lazily in a just-in-time fashion to provide communication batching. This lazy update is possible because all vertices are coordinated by a synchronization technique: any vertex v must first acquire a shared resource (e.g., a token or a fork) from its neighbor u before it can execute. Consequently, for an m-boundary vertex u with a replica on its neighbor v ’s worker, u ’s worker can buffer remote replica updates until v wants to execute (i.e., requests the shared resource)—at which point u ’s machine will flush all pending remote replica updates (and ensure their receipt) before handing over the shared resource that allows v to proceed.

In contrast, synchronous computation models (BSP and sync GAS) hide updates from replicas until the next superstep. That is, replicas can be updated only after a global barrier. This means systems with synchronous models are limited to specialized synchronization techniques that keep replicas up-to-date by dividing each superstep into multiple sub-supersteps. This is significantly less performant than synchronization techniques for systems with asynchronous computation models, as detailed further in Section 6.

4.2 Single-Layer Token Passing

Single-layer token passing, considered in [33], is a simple technique that passes an exclusive global token in a round-

robin fashion between workers arranged in a logical ring. Each worker machine must execute with only one thread.

The worker machine holding the global token can execute both its m-internal and m-boundary vertices (Definition 1), while workers without the token can execute only their m-internal vertices. This prevents neighboring vertices from executing concurrently since each m-internal vertex and its neighbors are executed by a single thread, so there is no parallelism, while an m-boundary vertex can execute only when its worker machine holds the exclusive token.

To enforce condition C1, local replicas must be updated eagerly, while remote replicas of a worker’s m-boundary vertices can be updated in batch before a worker passes along the global token (as updates will arrive before the token). Per Section 4.1, this is possible with asynchronous computation models. Thus, for asynchronous models, single-layer token enforces conditions C1 and C2 and, by Theorem 1, provides serializability. However, this technique does not provide serializability for synchronous computation models as they cannot update local replicas eagerly.

4.3 Vertex-based Distributed Locking

Vertex-based distributed locking, unlike token passing, pairs threads with individual vertices to allow all vertices to attempt to execute in parallel. As motivated in Section 2.1, the key idea is to coordinate these vertices such that neighboring vertices do not execute concurrently, while also addressing issues such as deadlock and fairness.

This coordination is achieved using the Chandy-Misra algorithm [13], which solves the hygienic dining philosophers problem, a generalization of the dining philosophers problem. In this problem, each philosopher is either thinking, hungry, or eating and must acquire a shared fork from each of its neighbors to eat. Philosophers can communicate with their neighbors by exchanging forks and request tokens for forks. The “dining table” is effectively an undirected graph where each vertex is a philosopher and each edge is associated with a shared fork: a philosopher u must acquire $\deg(u)$ forks to eat. The Chandy-Misra algorithm ensures no neighbors eat at the same time, guarantees fairness (no philosopher can hog its forks), and prevents deadlocks and starvation [13]. Hence, condition C2 is enforced.

To enforce condition C1, local replicas are updated eagerly and, for remote replicas, each worker flushes its pending remote replica updates before any m-boundary vertex relinquishes a fork to a vertex of another worker. Then, per Section 4.1, vertex-based distributed locking provides serializability for asynchronous computation models. As we mentioned in Section 4.1, this solution is incompatible with synchronous models (BSP and sync GAS) because these models do not allow local replicas to be updated eagerly. However, applying the theory developed in Section 3, Proposition 1 shows that a constrained vertex-based locking solution can provide serializability for systems with synchronous models. We omit the proof due to space constraints. It can be found in the longer version of this paper [21].

PROPOSITION 1. *Vertex-based distributed locking enforces conditions C1 and C2 for synchronous computation models when the following two properties hold: (i) all vertices act as philosophers and (ii) fork and token exchanges occur only during global barriers.*

5. PARTITION AWARE TECHNIQUES

In this section, we show how partition aware synchronization techniques can address severe limitations of existing techniques. We then present our partition-based solution to demonstrate its significant performance advantages.

5.1 Preliminaries

Existing graph processing systems provide parallelism at each worker machine by pairing computation threads with either graph partitions or individual vertices.

For example, both Giraph and Giraph async (Section 2.2) assign multiple graph partitions to each worker machine and pair threads, each roughly equivalent to a CPU core, with available partitions. This allows multiple partitions to execute in parallel, while vertices in each partition are executed sequentially. We call such systems *partition aware*.

In contrast, GraphLab async uses over-threading to pair lightweight threads (called fibers) with individual vertices. Thus, it has no notion of partitions. The large number of fibers provides a high degree of parallelism and ensures that CPU cores are kept busy even when some fibers are blocked on communication.

Systems like GraphLab async are well-suited for very fine-grained synchronization techniques such as vertex-based distributed locking (Section 4.3). Partition aware systems like Giraph async are able to support partition aware techniques that, as we will show, take advantage of partitions to significantly improve performance. Since GraphLab async is not partition aware, it is unable to support such techniques.

Lastly, as we will show in the following sections, it is important for synchronization techniques implemented in partition aware systems to distinguish between p-internal and p-boundary vertices, defined as follows.

DEFINITION 4. *A vertex u is a partition boundary vertex, or p-boundary for short, if at least one of its neighbors v belongs to a different partition from u . Otherwise, u is a partition internal, or p-internal, vertex.*

5.2 Motivation

The two existing synchronization techniques described in Section 4 suffer from several major performance issues.

Token passing has minimal communication overheads but very limited parallelism (Figure 1): only one worker machine can execute its m-boundary vertices at any time. Having only one global token also results in poor scalability, because the size of the token ring increases with the number of workers, which leads to longer wait times. Moreover, the token ring is fixed: workers that are finished must still receive and pass along the token, which adds unnecessary overheads. This is especially evident in algorithms such as SSSP, where workers may dynamically halt or become active depending on the state of their constituent vertices. Thus, as we show in Section 7.3, single-layer token passing is too coarse-grained, which negatively impacts performance.

On the other hand, vertex-based distributed locking maximizes parallelism, by allowing all vertices to execute in parallel, but suffers significant communication overheads. Vertex-based locking requires, in the worst case, $O(|\mathcal{E}|)$ forks, where $|\mathcal{E}|$ is the number of edges in the graph ignoring directions (i.e., counting undirected edges once). This leads to significant communication overheads due to the forks and corresponding request tokens that must be sent between individual vertices. Furthermore, it is difficult to form large batches

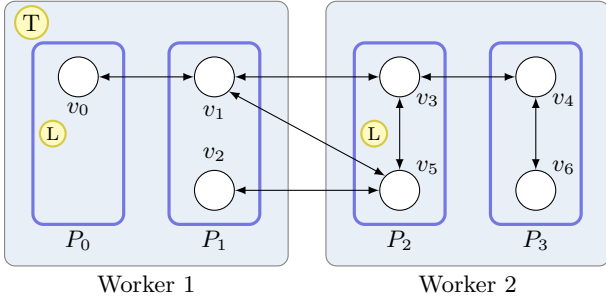

Figure 4: Dual-layer token passing, with the global token T at worker 1 and the local tokens L at partitions 0 and 2.

of messages (remote replica updates) as messages must be flushed very frequently, whenever an m-boundary vertex releases its forks. Although systems such as GraphLab async can use fibers to try to mask communication latency with additional vertex computations, it does not fully mitigate the communication overheads, which results in poor performance and scalability as we demonstrate in Section 7.3.

A key deficiency of these techniques is that they are not partition aware: given a partition aware system, they are unable to exploit partitions to improve performance. For example, single-layer token passing would pass the global token between the partitions rather than workers, with p-boundary vertices requiring the token to execute (Definition 4). This increases the size of the token ring and does not solve the existing performance problems. Similarly, vertex-based distributed locking (for asynchronous models) would require only p-boundary vertices to act as philosophers, since p-internal vertices are executed sequentially. However, although this reduces the number of forks, the heavy-weight threads will block an entire CPU whenever a vertex blocks on communication. Consequently, it is unable to mask communication latency and performs worse than GraphLab async’s pairing of fibers with individual vertices (Section 5.1).

We address these performance deficiencies by considering *partition aware* synchronization techniques. Adding partition awareness enables us to devise either a more fine-grained token passing technique to increase parallelism, or a more coarse-grained distributed locking technique to reduce communication overheads. We present these approaches next.

5.3 Dual-Layer Token Passing

We propose dual-layer token passing, which, unlike single layer token passing, supports multithreading by being partition aware. This enables more vertices to execute in parallel while ensuring condition C2 is enforced.

Dual-layer token passing uses two layers of tokens and a more fine-grained categorization of vertices. Let u be a vertex of partition P_u of worker W_u . Then an m-internal vertex u is now either a p-internal vertex, if all its neighbors belong to P_u , or a *local boundary* vertex otherwise. An m-boundary vertex u is either *remote boundary*, if its neighbors are only on partitions of other workers, or *mixed boundary* otherwise (i.e., its neighbors belong to partitions of both W_u and other workers). For example, in Figure 4, v_6 is a p-internal vertex, v_0 and v_4 are local boundary vertices, v_2 is a remote boundary vertex, and v_1 , v_3 , and v_5 are mixed boundary vertices.

A global token is passed in a round-robin fashion between

Figure 5: Partition-based distributed locking.

the workers. Each worker also has its own local token passed between its partitions in a round-robin fashion (Figure 4). A p-internal vertex can execute without tokens, while a local boundary vertex requires its partition to hold the local token. A global boundary vertex requires its worker to hold the global token and a mixed boundary vertex requires both tokens to be held. To ensure that every mixed boundary vertex gets a chance to execute, each worker must hold the global token for a number of iterations equal to the number of partitions it owns. Like single-layer token passing, local replicas are updated eagerly while remote replicas are updated before a worker relinquishes the global token. Hence, dual-layer token passing enforces conditions C1 and C2 for asynchronous computation models. Then, by Theorem 1, it provides serializability for asynchronous models.

Although dual-layer token passing improves parallelism by adding support for multithreading, it still suffers from the same performance issues as single-layer token passing. It again uses only one global token, has a fixed token ring, and scales poorly when the number of workers and/or partitions are increased. Having only one local token per worker also means local boundary vertices cannot execute in parallel.

While these problems may be solved via more sophisticated schemes, such as using multiple global tokens for more parallelism or tracking additional state to support a dynamic ring, it becomes much harder to guarantee correctness (no deadlocks and no starvation) while also ensuring fairness. Thus, rather than make token passing even more complex and fine-grained, we propose an inherently partition-based, coarse-grained distributed locking approach next.

5.4 Partition-based Distributed Locking

We propose partition-based distributed locking by building on the Chandy-Misra algorithm and treating partitions as the philosophers. Two partitions share a fork if an edge connects their constituent vertices. For example, in Figure 5, partitions P_0 and P_1 share a fork due to the edge between their vertices v_0 and v_1 , respectively. Alternatively, forks are associated with the virtual partition edges (in green), created based on the edges between each partition’s vertices.

Condition C2 is enforced for p-boundary vertices because neighboring partitions never execute concurrently, while p-internal vertices do not need coordination as each partition is executed sequentially. As an optimization, we can avoid unnecessary fork acquisitions by skipping the partitions for which all vertices are halted and have no more messages. To enforce condition C1, local replicas are updated eagerly and, for remote replicas, each worker flushes its pending remote replica updates before any partition (with an m-boundary vertex) relinquishes a fork to a partition of another worker.

Since both conditions are enforced, Proposition 2 follows immediately.

PROPOSITION 2. *Partition-based distributed locking enforces conditions C1 and C2 for asynchronous computation models.*

Hence, by Theorem 1, partition-based distributed locking provides serializability for asynchronous computation models. Synchronous models are not supported as they cannot update local replicas eagerly (Section 4.1), which is required due to the sequential execution of p-internal vertices.

Partition-based distributed locking needs at most $O(|P|^2)$ forks, where $|P|$ is the total number of partitions. By controlling the number of partitions, we can control the granularity of parallelism. On one extreme, $|P| = |V|$ can give vertex-based distributed locking (Section 4.3). On the other extreme, we can have exactly one partition per worker. This latter extreme still provides better parallelism than single-layer token passing because any pair of non-neighboring workers can execute in parallel, with a negligible increase in communication. In general, $|P|$ is set such that each worker can use multithreading to execute multiple partitions in parallel.

Due to this flexibility, partition-based locking is both more general and more performant than vertex-based locking: any choice of $|P| \ll |V|$ significantly reduces the number of forks and hence communication overheads. Moreover, partition-based locking enables messages (remote replica updates) of an entire partition of vertices to be batched, substantially reducing communication overheads. Compared to token passing, partition-based locking enables more parallelism: forks are required only between partitions that cannot execute in parallel, removing the need for a token ring, and halted partitions do not need their forks and will not perform unnecessary communication with their neighbors. These factors result in partition-based locking’s superior performance and scalability over both vertex-based distributed locking and token passing.

Hence, partition-based distributed locking leverages the best of both worlds: the increased parallelism of distributed locking and the minimal communication overheads of token passing. It scales better than vertex-based locking and token passing, due to its lower communication overheads and the absence of a token ring, and offers flexibility in the number of partitions to allow for a tunable trade-off between parallelism and communication overheads.

6. IMPLEMENTATION

We now describe our implementations for dual-layer token passing and partition-based distributed locking in Giraph, an open source graph processing system. Each technique is an option that can be enabled and paired with Giraph async to provide serializability. We show in Section 6.5 that providing serializability for AP does not impact usability. We do not consider the constrained vertex-based locking for BSP (Proposition 1) as it further exacerbates BSP’s already expensive communication and synchronization overheads [20].

We use Giraph because it is a popular and performant system used, for example, by Facebook [14]. It is partition aware and thus can support partition aware synchronization techniques. We do not implement token passing and partition-based distributed locking in GraphLab async because, as described in Section 5.1, GraphLab async is optimized for vertex-based distributed locking and is *not*

partition aware. Adding partitions would require substantial changes to the architecture, design, and functionality of GraphLab async, which is not the focus of this paper.

6.1 Giraph Background

As described in Section 5.1, Giraph assigns multiple graph partitions to each worker. During each superstep, each worker creates a pool of compute threads and pairs available threads with uncomputed partitions. Each worker maintains a message store to hold all incoming messages, while each compute thread uses a message buffer cache to batch outgoing messages to more efficiently utilize network resources. These buffer caches are automatically flushed when full but can also be flushed manually. In Giraph async, messages between vertices of the same worker skip this cache and go directly to the message store so that they are immediately available for their recipients to process.

Since Giraph is implemented in Java, it avoids garbage collection overheads (due to millions or billions of objects) by serializing vertex, edge, and message objects when not in use and deserializing them on demand. For each vertex u , Giraph stores only u ’s out-edges in u ’s vertex object. Thus, in-edges are not explicitly stored within Giraph.

6.2 Dual-Layer Token Passing

For dual-layer token passing, each worker uses three sets to track the vertex ids of local boundary, remote boundary, and mixed boundary vertices that it owns. p-internal vertices are determined by their absence from the three sets. We keep this type information separate from the vertex objects so that token passing is a modular option. Moreover, augmenting each vertex object with its type adds undesirable overheads since vertex objects must be serialized and deserialized many times throughout the computation. Having the type information in one place also allows us to update a vertex’s type without deserializing its object.

To populate the sets, we intercept vertices during input loading and scan the partition ids of its out-edge neighbors to determine its type. This is sufficient for undirected graphs but not for directed graphs: a vertex u has no information about its in-edge neighbors. Thus, we have each vertex v send a message to its out-edge neighbors u that belong to a different partition. Then u can correct its type based on messages received from its in-edge neighbors. This all occurs during input loading and thus does not impact computation time. We also batch all dependency messages to minimize network overheads and input loading times.

As per Section 5.3, the global and local tokens are passed in a round-robin fashion. Each local token is passed among its worker’s partitions at the end of each superstep. Since local messages (between vertices of the same worker) are not cached, local replicas are updated eagerly. For remote replicas, workers flush and await delivery confirmations for their remote messages before passing along the global token.

6.3 Partition-based Distributed Locking

For partition-based distributed locking, each worker tracks fork and token states for its partitions in a dual-layer hash map. For each pair of neighboring partitions P_i and P_j , we map P_i ’s partition id i to the id j to a byte whose bits indicate whether P_i has the fork, whether the fork is clean or dirty, and whether P_i holds the request token. Since partition ids are integers in Giraph, we use hash maps optimized

for integer keys to minimize memory footprint.

In the Chandy-Misra algorithm, forks and tokens must be placed such that the precedence graph, whose edge directions determine which philosopher has priority for each shared fork, is initially acyclic [13]. A simple way to ensure this is to assign each philosopher an id and, for each pair of neighbors, give the token to the philosopher with the smaller id and the dirty fork to the one with the larger id. This guarantees that philosophers with smaller ids initially have precedence over all neighbors with larger ids, because a philosopher must give up a dirty fork upon request (except while it is eating). Partition ids naturally serve as philosopher ids, allowing us to use this initialization strategy.

For directed graphs, two neighboring partitions may be connected by only a directed edge, due to their constituent vertices. Since partitions must be aware of both its in-edge and out-edge dependencies, workers exchange dependency information for their partitions during input loading. Like in token passing, dependency messages can be batched to ensure a minimal impact on input loading times.

Partitions acquire their forks synchronously by blocking until all forks arrive. This is because even if all forks are available, it takes time for them to arrive over the network, so immediately returning is wasteful and may prevent other partitions from executing (a partition cannot give up clean forks: it must first execute and dirty them). Finally, per Section 5.4, each worker flushes its remote messages before a partition sends a shared fork to another worker’s partition.

Using the insights from our implementation of partition-based distributed locking, we can also implement vertex-based distributed locking, which is the special case where $|P| = |V|$ (Section 5.4). Each worker tracks fork and token states for its p-boundary vertices and uses vertex ids as the keys for its dual-layer hash map. Keeping this data in a central per-worker data structure, rather than at each vertex object, is even more important than in token passing: forks and tokens are constantly exchanged so their states must be readily available to modify. Storing this data at each vertex object would incur significant deserialization overheads. Fork and token access patterns are also fairly random, which would further incur an expensive traversal of a byte array to locate the desired vertex.

Like the partition-based approach, for directed graphs, each vertex v broadcasts to its out-edge neighbors u so that u can record the in-edge dependency into the per-worker hash map. This occurs during input loading and all messages are batched. Vertices acquire their forks synchronously and each worker flushes its remote messages before any m-boundary vertex forfeits a fork to a vertex of another worker. However, as we show in Section 7, these batches of remote messages are far too small to avoid significant communication overheads.

6.4 Fault Tolerance

For fault tolerance, we use the existing checkpointing mechanism of Giraph. In addition to the data that Giraph already writes to disk at each synchronous checkpoint, we change Giraph to also record the relevant data structures (hash sets or hash maps) that are used by the synchronization techniques. For dual-layer token passing, each worker also records whether they have the global token and the id of the partition holding the local token. Checkpoints occur after a global barrier and thus capture a consistent state: there are no vertices executing and no in-flight messages.

Thus, neither token passing’s global token nor distributed locking’s fork and request tokens are in transit.

6.5 Algorithmic Compatibility and Usability

A system can provide one computation model for algorithm developers to code with and use a different computation model to execute user algorithms. For example, Giraph async allows algorithm developers to code for the BSP model and transparently execute with an asynchronous computation model to maximize performance [20]. Thus, with respect to BSP, the more efficient AP model implemented by Giraph async does not negatively impact usability.

When we pair Giraph async with partition-based or vertex-based distributed locking, it remains backwards compatible with (i.e., can still execute) algorithms written for the BSP model. To take advantage of serializability, algorithm developers can now code for a serializable computation model. Specifically, this is the AP model with the additional guarantee that conditions C1 and C2 hold. For example, our graph coloring algorithm is written for this serializable AP model rather than for BSP (Section 7.2.1).

However, not all synchronization techniques provide this clean abstraction. Token passing fails in this regard because only a subset of vertices execute in each superstep. That is, token passing cannot provide the guarantee that all vertices will execute some code in superstep i , because only a subset of the vertices will execute at superstep i . The same issue arises for the constrained vertex-based distributed locking solution for BSP and sync GAS (Proposition 1), because it relies on global barriers for the exchange of forks and tokens. In contrast, our implementations of partition-based and vertex-based locking ensure that all vertices are executed exactly once in each superstep and thus provide superior compatibility and usability.

7. EXPERIMENTAL EVALUATION

We compare dual-layer token passing and partition-based distributed locking using Giraph async and vertex-based distributed locking using GraphLab async. We exclude Giraph async for vertex-based locking because it is much slower than GraphLab async, up to $44\times$ slower on OR (Table 1). As discussed in Section 5.1, this is because GraphLab async is specifically tailored for the vertex-based technique whereas Giraph async is not. On the other hand, unlike Giraph async, GraphLab async is not partition aware and thus cannot support token passing or partition-based distributed locking. Hence, our evaluation focuses on the most performant combinations of systems and synchronization techniques.

7.1 Experimental Setup

To evaluate the different synchronization techniques, we use 16 and 32 EC2 r3.xlarge instances, each with four vCPUs and 30.5GB of memory. All machines run Ubuntu 12.04.1 with Linux kernel 3.2.0-70-virtual, Hadoop 1.0.4, and jdk1.7.0_65. We implement our modifications in Giraph 1.1.0-RC0 and compare against GraphLab 2.2, which is the latest version that provides serializability.

We use large real-world datasets^{2,3}[8, 7, 6], which are stored on HDFS as text files and loaded into each system using the default random hash partitioning. We use hash par-

tioning as it is the fastest method of partitioning datasets across workers and, importantly, does not favour any particular synchronization technique. Alternative partitioning algorithms such as METIS [24] are impractical as they can take several hours to partition large datasets [22, 30].

Table 1 lists the four graphs we use: **OR** and **TW** are social network graphs while **AR** and **UK** are web graphs. $|V|$ and $|E|$ of Table 1 denote the number of vertices and directed edges for each graph, while the maximum degree gives a sense of how skewed the graph’s degree distribution is. All graphs have large maximum degrees because they follow a power-law degree distribution.

For partition-based distributed locking, we use Giraph’s default setting of $|W|$ partitions per worker, where $|W|$ is the number of workers. Increasing the number of partitions beyond this does not improve performance: more edges become cut, which increases inter-partition dependencies and hence leads to more forks and tokens. Smaller partitions also mean smaller message batches and thus greater communication overheads. However, using too few partitions restricts parallelism for both compute threads and communication threads: the message store at each worker is indexed by separate hash maps for each partition, so more partitions enables more parallel modifications to the store while fewer partitions restricts parallelism and degrades performance.

7.2 Algorithms

We use graph coloring, PageRank, SSSP, and WCC as our algorithms. Our choice is driven by the requirements exhibited by graph processing algorithms that need serializability. As described in Section 1, many machine learning algorithms require serializability for correctness and convergence. SSSP is a key component in reinforcement learning while WCC is used in structured learning [29, 10]. Both algorithms are used with extensive parallelism, making convergence a crucial criterion that serializability can provide. Similarly, as established in Section 2, graph coloring falls into yet another class of algorithms where serializability ensures successful termination. Finally, PageRank is a good comparison algorithm for two reasons: first, existing systems that have considered serializability also implement PageRank [33, 18] and second, the simple computation and communication patterns of PageRank are identical to other more complex algorithms [4], which allows us to better understand the performance of the synchronization techniques without being hindered by algorithmic complexity.

7.2.1 Graph Coloring

We use a greedy graph coloring algorithm (Algorithm 1) that requires serializability and an undirected input graph. Each vertex u initializes its value/color as `NO_COLOR`. Then, based on messages received from its (in-edge) neighbors, u selects the smallest non-conflicting color as its new color and broadcasts it to its (out-edge) neighbors.

Algorithm 1 Graph coloring pseudocode.

```

1 procedure COMPUTE(vertex, incoming messages)
2   if superstep == 0 then
3     vertex.setValue(NO_COLOR)
4     return
5   if vertex.getValue() == NO_COLOR then
6      $c_{min} \leftarrow$  smallest non-conflicting color
7     vertex.setValue( $c_{min}$ )
8     Send  $c_{min}$  to vertex’s out-edge neighbors
9     voteToHalt()

```

In theory, the algorithm requires only one iteration since serializability prevents conflicting colors. In practice, because Giraph async is push-based, it requires three iterations: initialization, color selection, and handling extraneous messages. The extraneous messages occur because vertices indiscriminately broadcast their current color, even to neighbors who are already complete. This wakes up vertices, leading to an additional iteration. GraphLab async, which is pull-based, has each vertex gather its neighbors’ colors rather than broadcast its own and thus completes in a single iteration.

7.2.2 PageRank

PageRank is an algorithm that ranks webpages based on the idea that more important pages receive more links from other pages. Each vertex u starts with a value of 1.0. At each superstep, u updates its value to $pr(u) = 0.15 + 0.85x$, where x is the sum of values received from u ’s in-edge neighbors, and sends $pr(u)/\deg^+(u)$ along its out-edges. The algorithm terminates after the PageRank value of every vertex u changes by less than a user-specific threshold between two consecutive execution of u . The output $pr(u)$ gives the expectation value for a vertex u , which can be divided by the number of vertices to obtain the probability value.

We use a threshold of 0.01 for **OR** and **AR** and 0.1 for **TW** and **UK** so that experiments complete in a reasonable amount of time. Using the same threshold ensures that all systems perform the same amount of work for each graph.

7.2.3 SSSP

Single-source shortest path (SSSP) finds the shortest path between a source vertex and all other vertices in its connected component. We use the parallel variant of the Bellman-Ford algorithm [15]. Each vertex initializes its distance (vertex value) to ∞ , while the source vertex sets its distance to 0. Vertices update their distance using the minimum distance received from their neighbors and propagate any newly discovered minimum distance to all neighbors. We use unit edge weights and the same source vertex to ensure that all systems perform the same amount of work.

7.2.4 WCC

Weakly connected components (WCC) is an algorithm that finds the maximal weakly connected components of a graph. A component is weakly connected if all constituent vertices are mutually reachable when ignoring edge directions. We use the HCC algorithm [23], which starts with all vertices initially active. Each vertex initializes its component ID (vertex value) to its vertex ID. When a smaller component ID is received, the vertex updates its vertex value to that ID and propagates the ID to its neighbors.

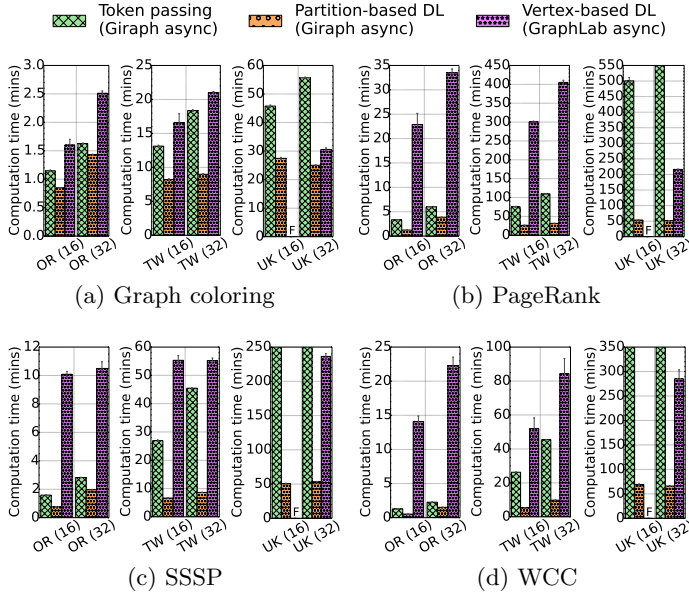

Figure 6: Computation times for graph coloring, PageRank, SSSP, and WCC. Missing bars are labelled with ‘F’ for unsuccessful runs.

7.3 Results

For our results, we report computation time, which is the total time of running an algorithm minus the input loading and output writing times. This also captures any communication overheads that the synchronization techniques may have: poor use of network resources translates to longer computation times. For each experiment, we report the mean and 95% confidence intervals of five runs (three runs for experiments taking over 3 hours). Due to space constraints, we exclude the results for AR. They can be found in [21].

For graph coloring, partition-based locking is up to $2.3\times$ faster than vertex-based locking for TW with 32 machines (Figure 6a). This is despite the fact that Giraph async performs an additional iteration compared to GraphLab async (Section 7.2.1). Similarly, partition-based locking is up to $2.2\times$ faster than token passing for UK on 32 machines. Vertex-based locking fails for UK on 16 machines because GraphLab async runs out of memory.

As detailed in Section 5.4, these performance gains arise from significantly reducing the communication overheads, which is achieved by sharing fewer forks between larger partitions instead of millions or billions of forks between individual vertices. Moreover, unlike vertex-based locking, partition-based locking is able to support message batching, which further reduces communication overheads.

For PageRank, partition-based distributed locking again outperforms the other techniques: up to $18\times$ faster than vertex-based locking on OR with 16 machines (Figure 6b). Vertex-based locking again fails for UK on 16 machines due to GraphLab async exhausting system memory. Token passing takes over 12 hours (720 mins) for UK on 32 machines due to its limited parallelism (Section 5.3), making partition-based locking over $14\times$ faster than token passing.

For SSSP and WCC on UK, token passing takes over 7 hours (420 mins) for 16 machines and 9 hours (540 mins) for 32 machines, while GraphLab async fails on 16 machines due to running out of memory (Figures 6c and 6d). For SSSP,

partition-based locking is up to $13\times$ faster than vertex-based locking for OR on 16 machines and over $10\times$ faster than token passing for UK with 32 machines. For WCC, partition-based locking is up to $26\times$ faster than vertex-based locking for OR on 16 machines and over $8\times$ faster than token passing for UK with 32 machines. These performance gains are larger because these algorithms, like many machine learning algorithms, require multiple iterations to complete: the per-iteration performance gains, described earlier, are further multiplied by the number of iterations executed.

Partition-based distributed locking also scales better when going from 16 to 32 machines. For example, partition-based locking achieves a speedup with graph coloring on UK, whereas token passing suffers a slowdown (Figure 6a). In the cases where partition based-locking also experiences slowdown, which occurs because serializability trades off performance for stronger guarantees, its performance does not degrade as quickly as token passing and vertex-based locking and its computation time remains the shortest.

Lastly, Giraphx implements its synchronization techniques only for graph coloring, so we can compare against only this algorithm. As discussed previously, Giraphx implements its techniques as part of user algorithms rather than within the system, resulting in poor usability as they must be re-implemented in every user algorithm. A key advantage of our techniques is that, because they are implemented at the system level, serializability is automatically provided for all user algorithms. For graph coloring on OR with 16 machines, Giraphx with single-layer token passing is $30\times$ and $41\times$ slower than Giraph async with dual-layer token passing and partition-based distributed locking, respectively. With vertex-based locking, Giraphx is $55\times$ slower than GraphLab async with vertex-based locking and $103\times$ slower than Giraph async with partition-based locking. On TW and UK, Giraphx fails to run due to exhausting system memory. Giraphx’s poor performance is due to its less efficient techniques, the fact that it uses a much older and less performant version of Giraph and, unlike Giraph async, does not implement the more performant version of the AP model.

8. RELATED WORK

To the best of our knowledge, this paper is the first to formulate the important notion of serializability for graph processing systems and to incorporate it into a foundational framework that has been implemented in a real system to deliver an end-to-end solution. Only Giraphx [33] and GraphLab [27, 18] provide serializability but, as we showed in this paper, our techniques significantly outperform their designs. Moreover, neither of their proposals provide a formal framework for reasoning about serializability nor do they show correctness for their synchronization techniques. Giraphx considers single-layer token passing and vertex-based distributed locking but its implementations are a part of user algorithms rather than within the system: each technique must be re-implemented in every user algorithm, which negatively impacts performance and usability. GraphLab async uses vertex-based distributed locking and is tailored for this synchronization technique. However, it is not partition aware and thus cannot support the more efficient partition-based distributed locking technique.

We mention several other vertex-centric graph processing systems next, however, they neither consider nor provide serializability. Apache Hama [2] is a general BSP system that,

unlike Giraph, is not optimized for graph processing. GPS [31] and Mizan [25] are BSP systems that consider dynamic workload balancing, but not serializability, while GRACE [35] is a single-machine shared memory system that implements the AP model. GraphX [36] is a system built on the data parallel engine Spark [37], and considers graphs stored as tabular data and graph operations as distributed joins. GraphX's primary goal is to provide efficient graph processing for end-to-end data analytic pipelines implemented in Spark. Pregelix [12] is a BSP graph processing system implemented in Hyracks [9], a shared-nothing dataflow engine. Pregelix stores graphs and messages as data tuples and uses joins to implement message passing. GraphChi [26] is a single-machine disk-based graph processing system for processing graphs that do not fit in memory.

9. CONCLUSION

We presented a formalization of serializability for graph processing systems and proved that two key conditions must hold to provide serializability. We then showed the need for partition aware synchronization techniques to provide serializability more efficiently. In particular, we introduced a novel partition-based distributed locking technique that, in addition to being correct, is more efficient than existing techniques. We implemented all techniques in Giraph to provide serializability as a configurable option that is completely transparent to algorithm developers. Our experimental evaluation demonstrated that our partition-based technique is up to $26\times$ faster than existing techniques that are implemented by graph processing systems such as GraphLab.

ABSTRACT

A traditional relational database can evaluate complex queries but requires users to precisely express their information need. But users often do not know what information is available in a database, and hence cannot correctly express their information need. Traditional databases do not provide convenient means for users to gain familiarity with the data.

In this paper, we study the problem of exploratory search, which a user may wish to perform to get an understanding of the data set. We note that users often have some decisions already made, so what they need is not an overall database summary, but rather a summary “in context” of the relevant portion of the database. Towards this end, we devise a novel data summarization technique called the Conditional Attribute Dependency (CAD) View, which shows the conditional dependencies between attribute values conditioned on applied selections. The CAD View can help users to gain familiarity with structured datasets in an attribute-wise manner.

To evaluate the CAD View, we perform a user study comprising three complex exploratory tasks on a real dataset. Our studies show that users are able to do all the tasks about 4-5 times faster and with better accuracy using the CAD View compared to the data summary shown in faceted navigation, which is currently the most popular search interface for e-commerce and has support for exploratory search.

1. INTRODUCTION

Users today have access to many large databases, yet find it difficult to access the records they want. In some cases, the challenge is to write correct SQL. But databases today often come with easy-to-use query interfaces. Users still find it difficult to specify the precise query conditions, due to limited familiarity with the data. Consider, for example, a user on a travel web site looking to book a hotel in a big city. If she knows her preferences for price, location, star rating, and other such relevant attributes, she can easily specify a query that will pull out a few good choices for

her to consider from among the hundreds of hotels in the city. But, if she is unfamiliar with the city, she may not understand what typical prices are in the city or how all the 5-star hotels are clustered in the financial district or how there is a tradeoff between location and price. Without this knowledge of the data in the database, she is forced to depend on other data sources, such as advice from friends and relatives, social media, web documents, etc., to gain data familiarity and pose the right queries. In consequence, even after hours of effort she may be left with various doubts: “Did I make a good choice?” “Did I explore all my options?” “Did I spend more than I needed to?”

Our goal in this paper is to develop database facilities to support exploratory search. There are two types of search: *lookup* and *exploratory* [26, 24, 19]. In lookup search users have a specific well-defined search goal. In contrast, in exploratory search, the users’ goal is to gain a comprehensive understanding of data that will enable them to pose more informed lookup queries.

Supporting data exploration is difficult because: (a) Datasets are complex and heterogeneous, and (b) Users have diverse needs. It is easy, for example, to provide the user with some simple summary statistics, such as average price for a hotel room. However, this number is of only limited value to the user, perhaps because there is huge variance between different parts of the city or perhaps because the user is a backpacker looking for youth hostels whose price is poorly correlated with those at fancy hotels. What the user needs is a characterization of a portion of the data (which she has identified to the system) along dimensions that are of interest to her.

Let us consider an example task to better appreciate our problem. For variety, we describe a car purchase task rather than a hotel room booking task. For specificity, we write all queries in SQL, even though we expect any real implementation to have a user-friendly interface layer on top the query language.

EXAMPLE 1. Consider a used car database, which contains a single table \mathcal{D} with n attributes where each tuple represents a car for sale. The table has numerous attributes that describe details of the car, such as Price, Make, Model, BodyType, Drivetrain, Mileage, EngineSize, NumCylinders, Color, FuelEconomy, Power, Year, etc.

Consider a user Mary who is unfamiliar with cars and wants to buy a relatively new SUV car. She has five initial Make preferences (Ford, Chevrolet, Toyota, Honda and Jeep), because she has friends who drive these Makes, but she is open to explore any similar option. She starts her exploration

with an initial query: $R = \text{SELECT } * \text{ FROM } \mathcal{D} \text{ WHERE Mileage BETWEEN } 10K \text{ AND } 30K \text{ AND Transmission = Automatic AND BodyType = SUV}$. This query leads to a large result set with thousands of tuples. Mary has to specify more constraints to get to a smaller result set that she can explore in depth. She thinks a good place to start may be to reduce the number of **Makes** she considers. Let’s look at her difficulties in choosing between **Makes**.

Limitation 1. Understanding Attribute Values —

The attribute **Make** has more than 50 values. Even to choose among the 5 **Makes** she has initially chosen, she needs to understand what is the main difference between SUVs from any pair of manufacturers, such as **Jeep** and **Chevrolet**. Furthermore, Mary knows that her initial set of 5 **Makes** is just a rough starting point, so before she narrows it down further she may also want to understand what other **Makes** are similar, and therefore belong in her consideration set. For example, she may want to know who else makes SUVs very similar to those made by **Chevrolet**.

Comparison can be of two types: *independent* and *conditional*. An independent comparison would be comparing the general characteristics of **Chevrolet** vs. **Jeep** cars. A conditional comparison would be based on the user’s already made selections. For example, Mary might want to compare the five **Makes**: **Ford**, **Chevrolet**, **Toyota**, **Honda** and **Jeep**, given the following choices: **BodyType** = **SUV**, $10K \leq \text{Mileage} \leq 30K$, **Transmission** = **Automatic**. Conditional comparisons are difficult even for users who are quite familiar with the domain. For example, Mary might know what **Make** she would prefer if there are no constraints on other attributes. However, if there are constraints in other attributes, such as **Price**, **Year**, **Color**, etc., it is hard to find **Makes** that will lead to cars that maximally satisfy her preferences across all the attributes.

With traditional relational database, result sets are presented as sets of tuples. To compare **Chevrolet** SUVs with **Jeep** SUVs, Mary has to look at hundreds of instances in each set. This is very difficult to do. Perhaps these tuples could be sorted on some important attributes, such as **Price**, so that corresponding tuples can be compared. But this requires knowing enough of the database to choose important attributes, and even so provides only limited assistance in understanding.

Finding similarities and differences are two complementary aspects of comparison. We looked at the difference case in the preceding paragraph. To find additional similar **Makes** is even more difficult, because now we need to check the hundreds of **Chevrolet** instances with the thousands of instances from dozens of other manufacturers. We note further Mary has a desired mileage range initially specified. As she explores the data set, she may decide to change this. If she is comparing **Makes** conditioned on her mileage selection, then she has a whole new comparison. The conditional comparisons change with every change in the given query condition.

Limitation 2. Querying Hidden Attributes — Often, there are characteristics of the data item that are important to the user but not explicitly recorded as an attribute in the database. For example, Mary wants to choose a certain car body look, but this field is not encoded anywhere in the database. There may be a way to express her preference as a selection on available attributes (perhaps as a combination

of low height, large wheel diameter and four doors). But Mary does not know how to express her desired look in terms of these other attributes.

Even worse, many database interfaces, for the sake of simplicity, may limit the number of queriable attributes. The number of cylinders in the engine may be an attribute recorded in the database, but it is not available to Mary through her forms-based interface for querying the database. It is possible that queriable attributes, such as fuel efficiency, can be used as surrogates to express her preference for a 4 cylinder engine. However, such cross-attribute relationships are completely opaque to Mary, and she is unable to substitute the surrogate for her desired attribute.

In exploring a database, users have two problems: (a) Choosing attributes that will enable them to efficiently and precisely reach to their desired result set, and (b) Choosing attribute values for each chosen attribute. These choices are challenging because there is complex dependency between attribute values within and across attributes, and users also have an unspecified, complicated preference function that spans across multiple attributes. Moreover, their preference function changes on seeing the comparison between available choices.

In short, while exploring a data set, users often make choices in sequence (with some backtracking where needed). They need help to understand the fragment of the database that is currently selected, and they would like to see this fragment of the data set characterized in terms of the choices (of attributes and attribute values) that the user is contemplating next. The alternation of browsing and querying in user interaction with data has been well-documented, where the purpose of browsing is mostly exploration. When data sets become large, unfortunately, browsing is no longer effective because of the very large number of tuples to be viewed. Therefore, this understanding of selected database fragment is best provided as a context-sensitive summary that supports the user’s exploration need.

In this paper, we present a novel data summarization technique called the *Conditional Attribute Dependency* (CAD) View, which allows users to systematically explore the conditional dependencies between attribute values both within and across attributes. It thereby lifts the two limitations described in the motivating example above. Our proposed CAD View can be integrated with any structured data presentation system.

Our key contributions are as follows:

- We identify two limitations that users face in exploring databases due to limited data familiarity (Section 1).
- We propose a query model and a data summarization technique called the CAD View that can help users gain familiarity with structured datasets (Section 2).
- We present the algorithms and techniques necessary to create and present the relevant CAD Views (Sections 3 and 4).
- We integrate CAD View with faceted navigation to make the exploratory search process user-friendly. Moreover, this also leads to a novel search interface that can support both exploratory and lookup search. (Section 5).
- We evaluate the CAD View on real data with a detailed user study. We find that users, on average, can perform

Make	Compare Attrs.	IUnit 1	IUnit 2	IUnit 3
Chevrolet	Model	[Traverse LT] [Equinox LT]	[Suburban 1500 LT, Tahoe LT]	[Captiva LS, Equinox LT]

Table 1: This table shows a sample Conditional Attribute Dependency (CAD) View for comparing five different car manufacturers. The first column Make is the Pivot Attribute. The second column Compare Attributes shows the top-5 attributes that are most informative for comparing the five Makes. The last three columns shows the top-3 IUnits for each Make. The user has selected BodyType = SUV, $10K \leq \text{Mileage} \leq 30K$, Transmission = Automatic. Each IUnit is a cluster label that summarizes a group of similar SUVs.

tasks that require data understanding with 4-5 times greater efficiency and accuracy using our CAD View as compared to faceted interface (Section 6).

Finally, we conclude with Section 8 after a discussion of related work in Section 7.

2. SOLUTION ARCHITECTURE

In this section we describe our solution to the exploratory search problem in complex databases — the *Conditional Attribute Dependency* (CAD) View. We also identify algorithmic challenges that must be solved for the CAD View to fulfill its goals.

2.1 The CAD View

The CAD View is a novel data summarization technique that shows the conditional relationship between values in a given attribute with values in other attributes. It is best introduced by example. A more formal treatment follows in the next subsection.

2.1.1 Overview

Table 1 shows a sample CAD View, obtained from a real dataset, for the example query discussed in Section 1. Mary’s goal was to explore automatic transmission SUV cars that have Mileage between 10K-30K from five different Makes. The CAD View has several important components:

- 1. The Pivot Attribute** organizes the information that is shown in the CAD View. A user explicitly chooses one of the attributes as *Pivot Attribute* f_p and requests the system to create a CAD View that facilitates comparison among attribute values selected from the Pivot Attribute by showing their relationship with values across other attributes. In Table 1, Mary has chosen Make as the Pivot Attribute.

- 2. Compare Attributes** are data attributes that interact with the Pivot Attribute in “interesting” ways. All the

values in the Pivot Attribute are compared using the same set of Compare Attributes. These attributes can be automatically determined based on the result set and the Pivot Attribute or explicitly provided by the user. For example, one can use correlation to quantify interesting interaction. In Table 1, the system has given five Compare Attributes: Model, Engine, Price, Drivetrain, and Year.

- 3. An IUnit** (Interaction Unit) is an “interesting” group of values for the Compare Attributes. In Table 1, each IUnit is described using the five Compare Attributes mentioned above. Each IUnit is chosen to be relevant to a Pivot Attribute value: Chevrolet, Ford, Honda, etc. The top-left IUnit in this table (containing Traverse LT and Equinox LT) identifies a set of mid-sized Chevrolet SUVs: they share an engine size and a drivetrain, and have similar prices. One can think of an IUnit as a cluster of database values with two special differences: it is a cluster on a partition of the database determined by each Pivot Attribute value, and the cluster is labeled using the chosen Compare Attribute labels and Compare Attribute values.

The Overall CAD View is a tabular combination of the above three components. It displays one row for each value of the user-selected Pivot Attribute. In the second column the system shows an ordered list of Compare Attributes, one for each row of the table. The rest of the table shows each row’s top IUnits, sorted left-to-right in descending order of relevance to the row’s Pivot Attribute value. If an IUnit cluster can be represented equally well by multiple values in a single Compare Attribute, then an IUnit will show multiple attribute values in square brackets (e.g. Traverse LT and Equinox LT).

Note that there are competing ways to rank IUnits from left-to-right within each row. They can be ranked left to right in order of their salience for the row’s Pivot Attribute value. Or we could try to ensure that all of the IUnits in a single column can be compared across all Pivot Attribute

values so that, *e.g.*, the IUnit 1 for **Chevrolet** is similar to IUnit 1 for **Ford** (and thereby addressing Limitation 1).

However, not all Pivot Attribute values may share comparable IUnits, forcing our system into an impossible tradeoff between IUnit quality and columnar IUnit “comparability.” Thus, we chose to rank IUnits strictly by their relevance to the row’s Pivot Attribute value. We use other means to satisfy the comparability goal as described below in Section 2.1.3.

2.1.2 Query Model

We use the following extension of SQL to express an exploratory search query:

```
CREATE CADVIEW cadview_name AS
  SET pivot = pivot_attr
  SELECT attr1, attr2,...,attrN
  FROM table1, table2...
  [WHERE Clause]
  [LIMIT COLUMNS M] [IUNITS K]
  [ORDER BY attr_name, attr_name ASC|DESC]
```

In the above expression, the list of attributes shown in the SELECT clause are the attributes that the user has explicitly selected as Compare Attributes. The LIMIT COLUMNS clause is used to limit the number of Compare Attributes. The CAD View will have total of M columns as Compare Attributes, in which N are explicitly provided by the user and the remaining (M-N) are automatically selected based on the query result and the Pivot Attribute. The number of IUnits per row K is determined using the keyword IUNITS. The ORDER BY keyword can be used to sort the IUnits by one or more columns.

```
CREATE CADVIEW CompareMakes AS
  SET pivot = Make
  SELECT Price
  FROM UsedCars
  WHERE Mileage BETWEEN 10K AND 30K AND
    Transmission = Automatic AND BodyType = SUV AND
    (Make = Jeep OR Make = Toyota OR Make = Honda OR
     Make = Ford OR Make = Chevrolet)
  LIMIT COLUMNS 5 IUNITS 3
```

For example, Mary’s query can be expressed as above. The Price attribute has been explicitly selected as a Compare Attribute, and the remaining four attributes (**Model**, **Engine**, **Drivetrain** and **Year**) are automatically determined.

2.1.3 Finding Similar Information

If there are V values in the Pivot Attribute and the user has requested k IUnits per attribute value, then the CAD View will have $k|V|$ IUnits. As discussed in Section 1, one of the primary goal of exploratory search is comparison, which includes finding similarities and differences. To facilitate comparison, we support the following two search operations within the CAD View: (i) Finding similar top ranked IUnits, and (ii) Finding similar attribute values within the Pivot Attribute.

For example, if a user likes a particular IUnit from one of the selected Pivot Attribute values (*e.g.*, **Chevrolet**), then the user may want to efficiently locate similar top-ranked IUnits that belong to other Pivot Attribute values. Similarly, if the user likes multiple IUnits of a particular Pivot Attribute value, then the user might be interested to find out other Pivot Attribute values that have similar IUnits.

Let’s say Mary likes IUnit 3 of **Chevrolet**. She can create a new CAD View where all the IUnits that are similar to this IUnit gets highlighted by using the following query:

```
HIGHLIGHT SIMILAR IUNITS
  IN CompareMakes
  WHERE SIMILARITY(Chevrolet, 3) > 3.5
```

In the similarity function the user gives the Pivot Attribute value and the IUnit ID. The above query will highlight all the IUnits (*e.g.*, IUnit 1 of **Ford**, IUnit 2 of **Jeep**) in the CAD View **CompareMakes** with similarity score greater than 3.5. As discussed later, for five Compare Attributes the max similarity score can be 5.0.

Similarly, to find **Makes** that are similar to **Chevrolet**, one can reorder the rows of the CAD View such that the Pivot Attribute values are ordered in terms of decreasing similarity with respect to **Chevrolet**. The similarity between two Pivot Attribute values can be measured by measuring the similarity between their IUnits. This query can be expressed as follows:

```
REORDER ROWS
  IN CompareMakes
  ORDER BY SIMILARITY(Chevrolet) DESC
```

2.1.4 Design Goals

We can now examine the extent to which the CAD View addresses the limitations described in the motivating example above:

Limitation 1. Understanding Attribute Values — With the traditional tuplewise presentation of result set, it was difficult for Mary to find the **Makes** that are similar to **Chevrolet**, or see the difference between **Chevrolet** and **Jeep**. However, using the CAD View it is easy to see that IUnits of **Chevrolet** and **Ford** are quite similar, and thus one can infer that both **Chevrolet** and **Ford** offer SUVs at roughly similar capacities and price points. One can also see that SUVs from **Chevrolet** and **Jeep** are quite different, and they primarily differ in **Price** and **Drivetrain**. Moreover, the CAD View can show conditional comparisons. Since Mary had selected **Mileage** between 10K and 30K, the CAD View shows her comparison between SUVs in **Year** range 2011-2012.

Limitation 2. Querying Hidden Attributes — Also recall that Mary was unable to choose cars with **V4** engines, because the interface did not expose **Engine** type as an option in the query panel even though the information was contained in the database (*i.e.*, **Engine** was a non-queriable attribute). Moreover, she was not familiar enough with the database to indirectly find **V4** engines by selecting values in the *queriable* attributes. In contrast, the CAD View identifies **V4** engines as a characteristic of specific IUnits for each body style. Mary can select the desired tuples using the corresponding queriable attributes.

2.2 Problem Definition

2.2.1 Assumptions

The CAD View is a tabular structure whose size must be small enough for the summary information to be absorbed effectively by the user. For example, the width must be small enough not to require horizontal scrolling when displayed on the user’s screen. We reflect this constraint on the width by limiting the number of IUnits we can show for each attribute

value. Let this number be k . We assume that k is given to us, either by the user explicitly, or through the system gaining knowledge of the user’s set up.

The length of the table must also be constrained for the same reason. There are two variables that control table length. The first is the number of distinct values for the pivot attribute. By default, we will show all of them. If the user is focused on only specific values, these can be listed explicitly in the CAD View specification. Mary has chosen 5 specific **Makes** in the example above. The second variable affecting table length is the number of Compare Attributes in each row. We assume that this number c is given to us, just as k is. Furthermore, if the user is interested in specific attributes, she can insist that these be included in the Compare Attributes that the system selects.

For categorical attributes or attributes with small discrete numerical domain, the attribute values are directly obtained from the domain. Where the number of values is very large, such as for most numerical domains, ranges of values are binned together to create a small number of discrete attribute values. Such attribute value cardinality reduction is necessary for effective summarization. However, this cardinality does not itself play a role in the CAD View generation algorithm. Therefore, we mention it here as a pre-processing step, but do not go into details of exactly how this binning is done. We suggest following the well-developed techniques in histogram construction[17] for this purpose.

In this section we describe the problems that needs to be solved to create the CAD View. Our goals are (i) to populate this structure effectively, making the most of limited screen real-estate available, and (ii) to arrange and present the information populated in this structure to maximize its value to the user.

For the first goal, we have to find the best (i.e., most informative) Compare Attributes, the best IUnit clusters, and (for each IUnit) the best value labels to describe the IUnit’s data.

The CAD View structure already lays out IUnits in rows, one per attribute value for the Pivot Attribute. For the second goal, the system must further decide how to order IUnits within each row, how to indicate similarity between IUnits in different rows, and how to indicate similarities and differences between rows as a whole.

2.2.2 Creating the CAD View

The CAD View is created for a given result data set \mathcal{R} and a Pivot Attribute. Populating the CAD View entails one main task: obtaining the k IUnits of interest for each value of the pivot attribute. This task can be written formally as:

Problem 1 (Generate IUnits): *Given a result set \mathcal{R} , a Pivot Attribute f_p , a set of attribute values \mathcal{V} selected from f_p , and a threshold value k , find for each attribute value $v \in \mathcal{V}$ a list of k IUnits S^v , where $S^v = \{s_1^v, s_2^v, \dots, s_k^v\}$ and s_j^v is the j^{th} IUnit for attribute value v .*

The first task could be accomplished as finding k clusters with our favorite clustering algorithm. However, we observe that our goal is to explain the main structure of this fragment of the data set to the user. Therefore, there are two important ways in which we deviate from the basic problem statement above. The first is that we restrict the clustering to be on the basis of only the attributes selected as *Compare Attributes*. These are the attributes that will be displayed in

the CAD View. In other words, these are the attributes that will be used to label each cluster (IUnit). Therefore, it is the values of these attributes that we wish to have clustered together in each IUnit rather than some other attributes not shown to the user. The second point we note is that we are under no obligation to cover all points in the data set with the clusters produced. We do not want outliers to distort the clusters. To this end, we choose to solve the clustering problem with a larger number l , and then choose the top- k IUnits from among these l clusters. l can be chosen by iterating through all plausible l values and evaluating the quality of the resulting CAD View for each. Or it could be obtained as a system tuning parameter, such as $l = 1.5k$.

We can then restate the CAD View generation problem as the following sequence of sub-problems:

Problem 1.1 (Compare Attributes): *Given a result set \mathcal{R} , a Pivot Attribute f_p , and set of attribute values \mathcal{V} selected in f_p , find a subset of Compare Attributes \mathcal{I} s.t. \mathcal{I} generate the most contrast among values in \mathcal{V} .*

Choosing Compare Attributes is a feature selection problem [12, 22] with a specialized way of evaluating the quality of a feature: good features (that is, Compare Attributes) yield sharply contrasting IUnits across the different Pivot Attribute values. One can discriminate among Compare Attributes as follows: Given a multi-class problem, a feature X is preferred to another feature Y if X induces a greater contrast between the multi-class conditional probabilities than Y . X and Y are indistinguishable if they induce the same amount of contrast.

Problem 1.2 (Generate Candidate IUnits): *Given a result set \mathcal{R} , a Pivot Attribute f_p , a set of attribute values \mathcal{V} selected from f_p , a set of Compare Attributes \mathcal{I} , and a threshold value l , find for each attribute value $v \in \mathcal{V}$ a list of l candidate IUnits S^v , where $S^v = \{s_1^v, s_2^v, \dots, s_l^v\}$ and s_j^v is the j^{th} candidate IUnit for attribute value v .*

Problem 1.2 is now stated as a clustering problem, with each resulting cluster being a candidate IUnit. We finally need to choose k IUnits from among these l candidates.

Problem 2 (Top-k IUnits): *Given a list of IUnits S^v for attribute value v , and a preference function P , find the top- k IUnits T^v in S^v according to preference P , where $T^v = \{t_1^v, t_2^v, \dots, t_k^v\}$ and $T^v \subseteq S^v$.*

The IUnits could be ranked based on a function that is rooted in the clustering algorithm; for example, we could prefer “tight” clusters by ranking them in ascending order of minimum pairwise similarity. However, we can pursue some application-specific goals by ranking IUnit clusters in a manner that is distinct from the IUnit creation mechanism. For example, our car navigation interface might, by default, rank clusters in ascending order of cluster price. In contrast, the fleet manager for a taxi company might have a different preference function that ranks IUnits in descending order of car mileage. Therefore, we have defined this ranking in terms of a specific preference function. If no function is specified by the user, we can use a simple system default, such as cluster size.

2.2.3 Finding Similar Information

The two search operations within the CAD View can be stated as following two problems:

Problem 3 (Similar IUnits): *Given two attribute values*

x and y from the Pivot Attribute, and an IUnit t_i^x from T^x , find all IUnits t_j^y s.t. $t_j^y \in T^y$ and $\text{sim}(t_i^x, t_j^y) \geq \tau$.

We can use any similarity function for this purpose, and any user or system specified threshold τ . We describe the specifics of the similarity function in Section 4.1.

Problem 4 (Similar Attribute Value): *Given two attribute values x and y and their top- k list of IUnits T^x and T^y , find the similarity between x and y by measuring the similarity of their top- k IUnits.*

If a user shows preference for a particular attribute value, it implies that the user has liked most of the top- k IUnits that has been shown for that attribute value. The user would be interested to see other attribute values that have similar IUnits both in terms of content and rank. We describe the specifics in Section 4.2.

3. CREATING THE CAD VIEW

In this section, we describe how we create and sort IUnits (problems 1 and 2 above) for the CAD View.

3.1 Generating Candidate IUnits

Generating uniformly labeled IUnits consists of two steps: finding good Compare Attributes \mathcal{I} that can show contrast in Pivot Attribute values \mathcal{V} ; and then generating l IUnits for each value $v \in \mathcal{V}$.

3.1.1 Finding Compare Attributes

The problem of finding Compare Attributes is similar to feature selection in a multi-class classification problem. To provide efficient user interaction and understanding, we use a feature selection algorithm that is computationally efficient and returns all the relevant features.

To determine the number of Compare Attributes we consider two factors: the available screen space and the relevance score of each informative facet. The user’s available screen space determines the maximum number c of Compare Attributes that can be shown for any Pivot Attribute. However, all Pivot Attribute may not have c informative facets that have relevance greater than a required minimum threshold relevance score. A relevant Compare Attribute always provides additional useful information. However, if a Compare Attribute is not informative about the Pivot Attribute, including it will lower the quality of generated IUnits and waste valuable screen space.

We use the ChiSquare feature selection algorithm [23]. ChiSquare evaluates the worth of an attribute by computing the value of the chi-squared statistic with respect to the class. For ChiSquare test one can determine the threshold relevance using p-values, such as significance level equal to 0.01, 0.05, or 0.10. Even with this simple technique, ranking Compare Attributes in order of decreasing relevance yields a few interesting observations that a typical user might not know. For example, it might seem that **Mileage** should be the best Compare Attribute when distinguishing among different **Year** values: older cars will naturally accrue more miles. However, it turns out that **Model** is better, as specific car models (Suburban 1500 LT, not simply Suburban) are released frequently, and a specific model is prominent in the database for only a short period of time.

3.1.2 Finding Important Attribute Interactions

To create IUnits for a Pivot Attribute value $v \in \mathcal{V}$, we take all tuples from the result set \mathcal{R} that contain the given value v , and allocate those tuples to l clusters. We derive an IUnit from each of these l clusters. We cluster the tuples using only the above-chosen Compare Attributes.

Since the CAD View is a user-facing application, we want to create it within interactive time limits, well under 1 sec. There are various factors that can slow down a clustering algorithm: (i) clustering a dataset with large numbers of tuples or dimensions, (ii) trying to infer the ideal number of clusters using the clustering algorithm, and (iii) clustering with large numbers of cluster centers. Since there are standard existing techniques to address each of these factors, we defer their discussion to experimental evaluation (Section 6.3).

The quality of IUnits depends on the quality of the clustering algorithm. Since both efficiency and quality are major concerns of our system, we use standard k-means algorithm. Our main contribution in the clustering step is the dynamic variation of system parameters to achieve real-time performance, as discussed later in Section 6.3.

Our key contribution in creating the IUnits is the post-clustering step of cluster labeling, which is often ignored in clustering research. Although clustering is a very nice data-categorization technique, it is very hard for most users to understand the large amount of information that is contained in each cluster, or be able to compare multiple clusters.

There are existing systems to visually explore clusters of structured data [5, 21, 29]. Some of these systems are not easy to explore when the data is high-dimensional or categorical. For normal end-users, the commonly used cluster labeling technique is to show the centroid of each cluster, which is useful when all clusters are spherical. For complex shaped clusters, it is considered more informative to show multiple tuples that can show the whole cluster boundary [5]. It is very hard to understand a high-dimensional cluster by seeing just one centroid or some boundary points. When a user sees a high-dimensional representative tuple, it is not easy to infer the dimensions that are most significant. We need to label the clusters in such a way that we can convey large amount of information in a summarized manner and also emphasize the important information.

The way we label the clusters has many benefits. We label all IUnits uniformly and use ranking at all levels. We rank the Compare Attributes to highlight the attributes that are most significant. Similarly, in each IUnit we rank the Compare Attribute values and show only the most important representatives. Instead of showing few representative tuples from each cluster, we try to summarize statistical distribution of each Compare Attribute. To label both categorical and numerical attributes in uniform manner, we discretize the numerical attributes. We rank attribute values based on frequency count and then group multiple values if they have similar frequency count. We use two thresholds — max display count and statistical difference between frequency counts — to determine the representative Compare Attribute values for each cluster.

3.2 Top- k IUnits

Without an explicit user preference function, we choose a preference function that depends on the size of the IUnit’s underlying cluster, as well as overall result diversity. IUnits that represent large clusters are desirable because they

summarize attribute interactions for larger number of tuples. Moreover, they may give more reliable insight than smaller outlier-prone clusters. However, when we select the top- k IUnits based purely on the cluster size, many are quite similar and appear redundant to the user.

Thus we use the generic top- k algorithm proposed in [25] to compute diversified top- k IUnits. It requires the following measures: preference score of each IUnit s_i^x , denoted as $\text{score}(s_i^x)$; similarity between two IUnits s_i^x and s_j^y , denoted as $\text{sim}(s_i^x, s_j^y)$; and a user defined threshold similarity value τ . Two IUnits s_i^x and s_j^y are considered similar, denoted as $s_i^x \approx s_j^y$, if $\text{sim}(s_i^x, s_j^y) \geq \tau$.

Diversified Top- k IUnits: Given a list of IUnits $S^v = \{s_1^v, s_2^v, \dots\}$ for a attribute value v , and an integer k , the diversified top- k IUnits for v , denoted as $T^v = \{t_1^v, t_2^v, \dots\}$, is the list of IUnits that satisfy the following conditions:

- 1) $T^v \subseteq S^v$ and $|T^v| \leq k$
- 2) For any two different IUnits s_m^v and s_n^v , if $s_m^v \approx s_n^v$ then $\{s_m^v, s_n^v\} \not\subseteq T^v$
- 3) $\sum_{t_i^v \in T^v} \text{score}(t_i^v)$ is maximized.

To create the CAD View, we need to compute the diversified top- k IUnits for each attribute value v . The diversified top- k problem can be reduced to the NP-Hard maximum independent set problem on graphs [25]. Greedy solutions often lead to good approximate results in many NP-Hard problems, but for this problem a greedy algorithm can lead to arbitrarily bad solutions, with no bounded constant factor solution [25]. Because in our problem the size $|S^v|$ is generally not large, Qin, *et al.*'s basic **div-astar** algorithm works well.

4. FINDING SIMILAR INFORMATION

In this section, we describe how to find similar components in the CAD View. These are solutions to Problems 3 and 4.

4.1 Finding Similar IUnits

If a user likes one of the IUnits, say IUnit t_i^x from T^x , the user can find all the IUnits t in the CAD View s.t. $t_i^x \approx t$ (in other words, $\text{sim}(t_i^x, t) \geq \tau$). This approach allows us to address the IUnit sorting problem mentioned in Section 2.1.1; we can now sort IUnits from left-to-right by order of salience to the row's Pivot Attribute value, while still allowing the user to compare similar IUnits.

Computing similarity between IUnits is equivalent to computing similarity between clusters. For a numerical dataset, one can compute cluster distance by measuring the distance (such as Euclidean distance) between cluster centroids. For a categorical dataset, one can use any distance measure that is used in existing categorical clustering algorithms to compute cluster distance [11]. However, things become more complicated when we have a mixed dataset, having both numerical and categorical attributes. The distance measure that is used in categorical datasets is quite different compared to those used in numerical datasets. To compute similar IUnits, we propose a new distance measure that can treat both numerical and categorical attributes in a uniform manner. We use discretization to convert numerical attributes into categorical attributes. Then we use a modified form of *cosine-similarity* to compute IUnit similarity.

Let t_i^x and t_j^y be two top- k IUnits for selected attribute values x and y , and \mathcal{I} be their set of Compare Attributes. We measure the similarity of t_i^x and t_j^y by summing their cosine

Algorithm 1 IUnit Pair Similarity

Input: t_i^x : IUnit 1
 t_j^y : IUnit 2
 \mathcal{I} : set of informative dimensions
Output: s : similarity between the two IUnits
Method:

- 1: $s \leftarrow 0$
- 2: **for all** $d \in \mathcal{I}$ **do**
- 3: $s \leftarrow s + \text{cosine-similarity}(t_i^x.d, t_j^y.d)$
- 4: **end for**
- 5: **return** s

similarities along each dimension d s.t. $d \in \mathcal{I}$. We use the frequency count of each attribute value in the corresponding cluster as the attribute value's term frequency. Since the range of *cosine-similarity* function is $[0, 1]$, the range of the above similarity function is $[0, |\mathcal{I}|]$. Based on the specific data domain, one can choose the IUnit similarity threshold value τ as some $\alpha \cdot |\mathcal{I}|$, where $\alpha \in (0, 1)$.

Algorithm 2 Attribute-value Pair Similarity

Input: $T^x = \{t_1^x, t_2^x, \dots, t_k^x\}$ top- k IUnits for attribute value x
 $T^y = \{t_1^y, t_2^y, \dots, t_k^y\}$ top- k IUnits for attribute value y
Output: d : distance between T^x and T^y
Method:

- 1: $d \leftarrow 0$
- 2: **for all** $t_i^x \in T^x$ **do**
- 3: **if** $\exists t \in T^y$ s.t. $t \approx t_i^x$ **then**
- 4: $\text{index} \leftarrow j$ s.t. $t_i^x \approx t_j^y$ and $\arg\min_j |j - i|$
- 5: **else**
- 6: $\text{index} \leftarrow |T^y| + 1$
- 7: **end if**
- 8: $d \leftarrow d + |i - \text{index}|$
- 9: **end for**
- 10: **for all** $t_j^y \in T^y$ **do**
- 11: **if** $\exists t \in T^x$ s.t. $t \approx t_j^y$ **then**
- 12: $\text{index} \leftarrow i$ s.t. $t_i^x \approx t_j^y$ and $\arg\min_i |j - i|$
- 13: **else**
- 14: $\text{index} \leftarrow |T^x| + 1$
- 15: **end if**
- 16: $d \leftarrow d + |j - \text{index}|$
- 17: **end for**
- 18: **return** d

4.2 Finding Similar Attribute Values

If a user has preference for a Pivot Attribute value, the user can create a CAD View where the first row contains IUnits for the preferred value, and the remaining Pivot Attribute values are shown in decreasing order of similarity to the preferred value. Two attribute values are considered similar if their top- k IUnits lists are similar. Two ranked IUnit lists T^x and T^y should be similar if they have similar IUnits, and similar IUnits have similar rank.

To the best of our knowledge, there is no existing distance metric to compute similarity between two ranked lists having a disjoint set of items. In Algorithm 2, we propose a distance measure that can compute distance between two given ranked lists by taking into consideration the similarity between their items both in terms of information content and rank.

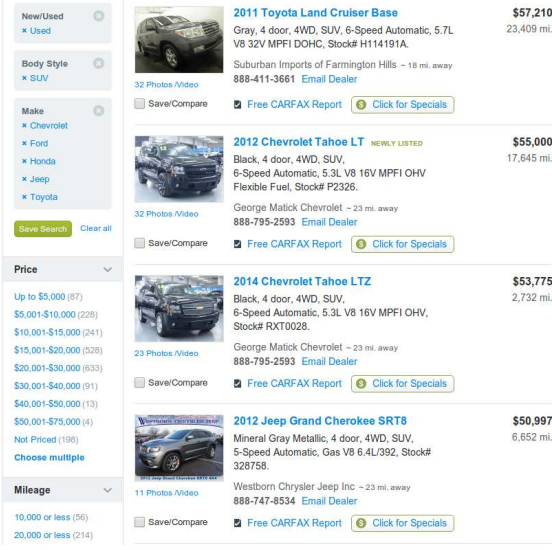

Figure 1: This screen capture from cars.com represents an example of a faceted navigation interface.

In lines 2-9, we compare how IUnits in T^x compare to IUnits in T^y . In line 3, we check whether the list T^y has some IUnit which is similar to IUnit t_i^x from T^x . If there is no similar IUnit (line 6), we assume that t_i^x is similar to the IUnit that has highest rank amongst non-selected IUnits (i.e., $S^y \setminus T^y$), and thus has rank $|T^y| + 1$. In lines 3-4, if there are multiple IUnits in T^y that are similar to t_i^x , then we take the IUnit whose rank is closest to rank of t_i^x in T^x , which is i . In line 8, we sum the rank differences for all IUnits in T^x . Lines 10-16 show the same steps for list T^y .

5. FACETED SEARCH WITH CAD VIEW

The CAD View defined above can be used with any relational database, independent of any front ends used. In fact, we have even suggested small SQL extensions to capture this concept. Nevertheless, we recognize that most end-users are unlikely to be SQL programmers, and are likely to be accessing relational data through some user-friendly interface. In this section, we consider one such popular interface, and describe how we have integrated CAD View with it.

Shoppers in e-commerce applications are a major target for our work: they are often exploring unfamiliar web sites before they actually buy. Since most e-commerce web sites use faceted navigation, that is the interface that we chose to integrate CAD View into. Figure 1 is a screenshot of a typical faceted interface for browsing a database of cars. In this section, we describe a novel two-phased faceted interface, called *TPFacet*, which integrates CAD View with faceted browsing.

A basic faceted interface has two main component panels: a query panel and a results panel. The latter typically occupies the majority of the screen real estate and shows the set of currently selected items. The former is usually on the left side, and offers both user interface controls as well as a summary digest of the current query and result set. This summary digest typically comprises all the attribute values (attribute values) that appear in the selected items, grouped by their corresponding attribute (attribute). The tuple count for each attribute value may also be included.

To fit the CAD View within users' limited screen space,

we propose a slightly changed interaction model for faceted navigation: at any one time, the interface will display either the results panel *or* the CAD View. The user explicitly toggles between them, though it is easy to imagine a system that intelligently chooses a default view, based on the size of query results. We imagine the user will interact with the system in two distinct phases: the *query revision* phase focuses on the CAD View, while the *result set* phase focuses on the results panel, with the user exploring individual items of interest in the result set.

Faceted navigation is an interaction based search system. We need to modify the faceted search interface so that users can create the CAD View or find similar components within the CAD View using interactive search techniques. We made the following three modifications: (i) Make each queriable attribute selectable (using html radio buttons) so that users can select them as Pivot Attribute, (ii) When users click on an IUnit in the CAD View we highlight all the other similar IUnits, and (iii) When users click a Pivot Attribute value in the CAD View we reorder all the rows in the CAD View in decreasing order of similarity w.r.t. the clicked attribute value. We call the faceted interface with these changes as TPFacet system.

6. EVALUATION

The goal of the CAD View is to facilitate exploratory search in complex datasets. As such, the primary evaluation of the CAD View is by means of a user study. In particular, we compare the use of the CAD View with a standard faceted interface for three exploratory search tasks. As a baseline for comparison, we use Apache Solr [2], which is a popular open source enterprise search platform. Apache Solr has support for faceted navigation and is used by many e-commerce sites. Apache Solr has many configuration settings. We chose a setting that is closest to the CAD View query model. We discuss the user study in depth in Section 6.2.

A secondary question is one of performance. Since the summaries shown in the CAD View are quite complex, we have to make sure that they can be computed in reasonable (interactive) time for the data set complexities and sizes that we expect. We discuss this issue in Section 6.3.

6.1 Implementation and Environment

We integrated the CAD View with Apache Solr to design the TPFacet system (see Section 5). We input the users' query from faceted interface, compute the CAD View and all similarity scores in the backend server, and return the resulting CAD View and similarity information using HTML and Javascript. To do feature selection and clustering, we use ChiSquare and SimpleKMeans algorithm respectively. Both algorithms are available in Weka [13].

We used two real datasets—YAHOOUSED CAR and MUSHROOM [9]—to do the evaluation. We scraped Yahoo's used car site [1] to create a table comprising 40,000 tuples with 11 attributes. The MUSHROOM dataset has 8124 tuples with 23 attributes. These numbers are at the lower end of what one sees in a typical e-commerce dataset. The CAD View will become more valuable in datasets that have more number of attributes or tuples. The MUSHROOM dataset is very popular in machine learning. It is simple to understand for a non-expert, since it describes familiar properties, such as color and smell, but has data that most of us (and all of our

users) have no knowledge of, forcing us to learn patterns by examining the data set afresh without reliance on previous knowledge.

6.2 User Study

We devised a diverse set of carefully specified information exploration tasks, described in the subsections that follow, each of which tests (some aspects of) the users’ understanding of the database. These tasks roughly correspond to the two motivating limitations discussed in Section 1. The first two tasks correspond to Limitation 1, where we evaluate users’ ability to perform comparisons in the form of finding differences and similarities respectively. The third task corresponds to Limitation 2, where we test users’ ability to query non-queriable attributes using available queriable attributes. We used the MUSHROOM data set, which was unfamiliar to all our users.

We compare TPFacet and Solr in terms of their usability in users’ task completion time and quality of response to given tasks. For all the tasks we report the results using statistical analysis.

We performed our user study using eight graduate students from our university. As we will see in the following subsections, statistical analysis show that the conclusions we draw from these eight users are statistically significant.

We gave all the users a demo explaining all features of the TPFacet and the steps to do the tasks using both the interfaces. We allowed the users to do the tasks remotely to minimize effect of any environmental factors. We created 3 matched pairs of tasks, one pair for each type described below. We divided the eight users into two equal groups. We indicate each user by their user id $U1-U8$. Users with id $U1-U4$ were assigned to group 1 and $U5-U8$ to group 2. For a task pair (A, B) we asked one of the groups to do task A using TPFacet and task B using Solr. We reversed the task assignment for the other group. In other words, if a task was done by group 1 users using Solr, then the same task was done by group 2 users using TPFacet, and vice versa.

For all the three tasks we have performed linear mixed model statistical analysis [28]. We use Display type as fixed effect and User ID as random effect. Computing p-values for mixed models aren’t as straightforward as they are for linear models. The most popular way to obtain p-value is to use the *Likelihood Ratio* test as a means to attain p-values. The logic of the likelihood ratio test is to compare the likelihood of two models with each other. First, the model without the factor that one is interested in (the null model) and then the model with the factor that one is interested in. By comparing these two models, one can determine whether the factor one is considering is significant or not. We use ANOVA to compare the two models.

6.2.1 Simple Classifier

This task illustrates the benefits of the CAD View in finding differences between attribute values. We asked users to build a simple classifier. Classification is an important machine learning problem where given a training data with multiple class labels, one builds a classification model by which one can find the set of classes (categories) a new test observation belongs. In this task, we build a classifier for binary class data. We assume a simple classification model that consists of selecting at most two attribute values that maximizes the number of tuples retrieved from a given

target class, and minimizes the number of tuples from the other class. Although problems like classification are rarely done manually for large datasets, human ability in this task demonstrates an understanding of crucial database themes. We evaluate the goodness of the classifier using standard F1 accuracy score. A sample task was to build a classifier for target class **Bruises** = true, where the given classes were **Bruises** = {true, false}.

Figure 2: Simple Classifier

Figure 3: Simple Classifier

Figure 2 shows the F1 scores for the classifiers that users got for this task. Statistical analysis shows that TPFacet affects the quality of classifier by ($\chi^2(1) = 5.572$, $p = 0.018$), increasing the F1 score by about 0.078 ± 0.0285 . Moreover, the variation in F1 score is much lower when users use the TPFacet system as compared to Solr because the exploration using TPFacet is more methodical. In Figure 3, we show the time taken by the users to build the classifiers. Statistical analysis shows that TPFacet affects the time taken by ($\chi^2(1) = 8.54$, $p = 0.003$), lowering it by about 5.44 ± 1.56 minutes.

6.2.2 Most Similar Facet Value Pair

This task illustrates the benefits of the CAD View in finding similar (or equivalent) attribute values. In this task, we gave users a list of four attribute values from an attribute and asked them to find the two most similar attribute values. For example, given attribute = **GillColor** and attribute values = {buff, white, brown, green}, find the two most similar gill colors.

In the traditional faceted interface, users can Compare Attribute values by comparing their summary digest. We gave users a cosine-similarity based distance metric to compare the summary digests. We asked users to select each of the given attribute values, one at a time, and compare their summary digest. In the CAD View, we didn’t show the computed similarity scores, but allowed users to use interactive effects to find similar IUnits and attribute values.

Figure 4 shows users response quality for this task. Since there are four attribute values, there are 6 possible attribute value pairs. We computed the defined similarity score for each pair and ranked them from 1 to 6, with the most similar pair being ranked as 1. Since computing exact similarity score is very hard for humans, we purposely chose attributes

Figure 4: Most Similar Attribute Value Pair

and attribute values that would make the task humanly feasible in Solr. The similarity between gill colors **brown** and **white** was so high as compared to other choices that all the eight users got correct answer for this task. Group 1 users (U1-U4) did this task using TPFacet and group 2 users using Solr. However, the other similarity task was slightly harder. For the other task, users U7 and U8 got the most similar attribute value pair according to attribute value similarity we defined in Section 4, but according to the metric defined in this task, they turned out to be second most similar pair. Statistical analysis shows that there is no difference in users response quality by using the two types of interface.

Figure 5: Most Similar Attribute Value Pair

Figure 5 shows the time users took to finish this task. Statistical analysis shows that TPFacet affects the time taken by ($\chi^2(1) = 12.04$, $p = 0.0005$), lowering it by about 6.00 ± 1.23 minutes. All users, except user U7, finished the task around four times faster using TPFacet as compared to Solr. Since the users were doing this task for the first time, some of them were trying to manually compare the IUnits. Users could have got the desired answer for this task much faster by just using the interactive effects, as seen in case of users U4, U8 and U1.

6.2.3 Alternative Search Condition

This task illustrates the benefits of the CAD View in querying non-queriable attributes using queriable attribute values. In this task, we gave users a set of selection conditions that lead to some result set \mathcal{R} . We asked users to find another set of selection conditions that would lead to same result set \mathcal{R} , but not using any of the already given selection conditions. One can see the given selection conditions as selection conditions on non-queriable attributes that the users cannot query. Only an informed user can precisely access the desired result set using an alternate option. A sample task was to find an alternative selection condition using at most two attribute values that would lead to the same result as selecting: **StalkShape** = **enlarged** and **SporePrintColor** = **chocolate**.

To evaluate users response quality, we checked the similarity between the query result obtained from the given selection condition and the users alternate selection condition. To measure similarity between the two results, we measured the similarity between their faceted summary digest.

Figure 6: Alternative Search Condition

Figure 6 shows users response quality for this task. Statistical analysis shows that TPFacet affects the users alternative search condition by ($\chi^2(1) = 3.28$, $p = 0.07$), lowering the retrieval error by about 0.329 ± 0.172 . Using TPFacet most users were able to do the task with five times lower retrieval error. In this task pair, the task that group 1 users did using Solr, turned out to be quite easier compared to the one they had to do using TPFacet. We can see this difference by seeing that users U3 - U8 have very low and similar error for this task. For the easier task, just one attribute value was sufficient to get to the desired result set. All the users in group 2 had come up with slightly variant solutions, but exactly the same retrieval error (48 missing tuples out of 1344). Since TPFacet allows users to do this type of task in more methodical approach compared to Solr, we find much lower variation in users response quality. For the slightly harder task, we see slight variation in retrieval error among group 1 users who did this task using TPFacet, but the error variation is much higher for group 2 users who did it using Solr. Group 2 users, such as U5, U6 and U8, who had much lower error compared to user U7 had to spend significantly more amount of time as seen in Figure 7.

Figure 7: Alternative Search Condition

Figure 7 shows the time users took to finish this task. Statistical analysis shows that TPFacet affects the time taken by ($\chi^2(1) = 2.58$, $p = 0.108$), lowering it by about 2.00 ± 1.14 minutes. Most users were able to do the task 1.5 to 2 times faster using TPFacet as compared to Solr. This task required more time because users had to manually differentiate the IUnits. The main benefit of TPFacet was that users didn't have to try various options using hit-and-trial. They had to look through the IUnits to find the discriminating attribute values, but then it was just trying very few possible alternate choices to see which one gives the best result.

6.3 Performance

Computational time is a crucial constraint for all user facing applications because users expect almost instantaneous response. In this subsection, we evaluate whether TPFacet can provide interactive responses. We performed all our performance experiments on the YAHOOUSED CAR dataset with 40K tuples and 11 attributes. When users browse over e-commerce sites, they rarely deal with result size that is more than 30K-40K tuples and 5-10 queriable attributes. Thus

we evaluate our system using all the tuples of our used-car dataset as query result, with all its attributes being used as queriable attributes.

Our experiments show that TPFacet can give acceptable performance by just using computationally efficient feature selection and clustering algorithms. Each of our experimental graphs are based on average readings of 50 simulations, where for each simulation we generate a different query result by randomly selecting a subset of tuples and/or attributes. The default parameters in these experiments are: the number of Compare Attribute $\mathcal{I} = 11$, the number of generated IUnits $l = 10$, the number of IUnits shown $k = 6$, and the number of attribute-values selected in the Pivot Attribute $\mathcal{V} = 5$. In these experiments, we assume that if the total size of the query result set is $|\mathcal{R}|$, then each attribute value $v \in \mathcal{V}$ has $|\mathcal{R}|/|\mathcal{V}|$ tuples.

Figure 8: Worst Case System Performance

Figure 8 shows the total time to compute the CAD View for different sizes of query result. In the shown graph, we do not do any optimizations, except using a computationally efficient feature selection and clustering algorithm, that can lead to better system performance. Moreover, we chose system parameter values to demonstrate the worst-case performance of our system. For example, we kept $|\mathcal{I}| = 11$ and $l = 15$. When we consider interaction between many attributes (large $|\mathcal{I}|$) or try to compute many interactions (large l), then it decreases system performance, as shown in later experiments. We divide the total time into three parts: time to compute Compare Attribute, time to generate IUnits and time for all remaining steps, such as top-k ranking, and similarity between IUnits and attribute-values, that we represent collectively as others. We can see that the most computationally intensive parts of TPFacet is computing the top Compare Attribute and generating candidate IUnits. Total time for all other steps is negligible because of the small values of k and $|\mathcal{V}|$ established due to user’s display constraint. We can see that even this naive solution is acceptable when the result size is less 15K. But as we increase the result set size, we can see that the time to compute CAD View increases and becomes almost 4.5 secs for 40K tuples. Since the result set size is likely to be the largest in the initial stages of exploration, and since this is also likely to be when the user really needs interactive response to freely try alternatives, a multi-second response time is too slow. To alleviate this problem, we developed several optimizations.

Optimization 1. Sampling — Sampling can improve both feature selection and clustering. For all our attributes, when we computed the set of top ranked Compare Attribute using a small random sample of size 5K-10K, we always got almost the same set, as we got from any larger sample size, including the full dataset. As shown in Figure 8, computing

Compare Attribute takes only 20-50 ms for 5K-10K tuples, as compared to 1700 ms for 40K tuples. Quality of Compare Attribute is more crucial when users are towards the end of their exploration, and at that time even the exact computation will take very short time due to small result size. Even if there were some degradation in quality due to sampling, it may not matter much in the initial stages. Similarly, we can also reduce the time for generating IUnits by generating IUnits from a small sample.

Figure 9: Number of Generated IUnits vs Time

Optimization 2. Varying Generated IUnits — Figure 9 shows the effect of number of generated IUnits l on computation time for different result sizes. We observed that as we increased the number of generated IUnits, it increases computation time due to increased time for clustering. For small 10K result size, computation time is small, less than 500 ms, even when we generate 15 IUnits per attribute value. However, if the result set is large and we generate large number of IUnits, as shown in Figure 8 for 40K tuples with $l = 15$, then it slows down system performance. When users are in their beginning stages of exploration, it is hard to know their preference because their query is too broad. Generating more IUnits and finally ranking is meaningful when we know users’ preference more precisely, which typically happens near the end-stages of exploration. Thus we generate fewer IUnits when the result set is very large, so that we can provide a good summary of all options. As users narrow down their exploration, we increase the number of generated IUnits and return better top- k IUnits.

Figure 10: Number of Compare Attributes vs Time

Optimization 3. Fewer Compare Attributes — Figure 10 shows the effect of number of Compare Attributes on computing clusters for different result sizes. As we increase the number of Compare Attributes, it increases computation time because we need to look at the interaction between larger number of attributes. By showing few Compare Attributes we can cluster even 40K tuples in less than 500 ms.

By combining all the above optimizations in creating the CAD View, we can greatly increase the performance of TPFacet system. For example, we can get an CAD View for 40K tuples in less than 500 ms.

7. RELATED WORK

Exploratory search [26, 27, 24, 19] has recently become an important research problem in IR, HCI and database communities. We defined a new exploratory search problem in databases. In evaluating exploratory search systems we cannot separate human behavior from the search system. Since users have diverse background knowledge and information need, it is difficult to evaluate exploratory search systems. Designing evaluation metrics and methodologies for exploratory search system is a challenging research problem [26]. We presented a detailed user-study, based on explicit exploration/understanding tasks with quantitative measures, to evaluate our system.

The CAD View is a summary of important interactions between attributes. Measuring attribute interactions is a part of broader feature selection problem [12, 22, 18] in machine learning. In databases, attribute interactions are often measured in form of functional dependencies [8, 16] and referential integrities. Although standard feature selection can find the interaction between attributes, a Bayesian network [15] can provide a more accurate description of attribute interactions by giving probabilistic dependencies between attributes. These techniques can be used to create CAD Views with other types of data summaries.

Large volumes of relational data are often summarized using data warehousing and OLAP technology [10]. There are also many data mining techniques, such as clustering [20, 3] and decision trees [4, 6], that can group data into meaningful groups according to some user given notion of similarity. A central property of these algorithms is that they depend on the data and are independent of the user's interest. Therefore, the results are often not related to the user's specific exploratory goal. In this paper, we presented a context dependent summarization technique.

Faceted categorization and clustering are both grouping techniques. Hearst [14] presents a nice comparison of how these two techniques complement each other. Various usability studies have shown that users prefer the predictable faceted categorization over clustering [7]. In this paper, we combined faceted browsing with clustering to build the TP-Facet system that has benefits of both faceted navigation and clustering.

8. CONCLUSION

In this paper, we presented an exploratory search system for relational databases. Our solution relies on a novel data summarization technique called the CAD View, which provides a context dependent summary of relational result set. We showed through an extensive user study that the CAD View can help users gain quick data familiarity with complex datasets. Although computing the CAD View is computationally intensive, we provided optimizations that enable it to be easily integrated with existing search interfaces, without compromising system performance.

ABSTRACT

Although existing database systems provide users an efficient means to select tuples based on attribute criteria, they however provide little means to select tuples based on *whether they meet aggregate requirements*. For instance, a requirement may be that the cardinality of the query result must be 1000 or the sum of a particular attribute must be $< \$5000$. In this work, we term such queries as “Aggregation Constrained Queries” (ACQs). Aggregation constrained queries are crucial in many decision support applications to maintain a product’s competitive edge in this fast moving field of data processing. The challenge in processing ACQs is the unfamiliarity of the underlying data that results in queries being either too strict or too broad. Due to the lack of support of ACQs, users have to resort to a frustrating trial-and-error query refinement process. In this paper, we introduce and define the semantics of ACQs. We propose a refinement-based approach, called ACQUIRE, to efficiently process a range of ACQs. Lastly, in our experimental analysis we demonstrate the superiority of our technique over extensions of existing algorithms. More specifically, ACQUIRE runs up to 2 orders of magnitude faster than compared techniques while producing a 2X reduction in the amount of refinement made to the input queries.

1. INTRODUCTION

Databases provide a number of ways to efficiently select tuples of interest to the user by constraining attributes of individual tuples, for instance, return tuples that meet the criteria price $< \$50$, join results between tuples in table A and table B that match on attribute “id,” etc. However, little effort has been focused on a means of selecting tuples based on *whether they satisfy aggregate constraints*. For instance, select tuples with average price $< \$10$, number of tuples = 1000, etc. The ability to apply aggregate constraints along with constraints on tuples’ individual attribute values is important in many applications as illustrated below.

- In advertising campaigns (such as Example 1), *the budget restricts the number of users that can be reached* [4]; as a result, the campaign manager must select users based not only on demographics but also whether the total number of users (i.e. the COUNT) is within the budget limit.

- In a supply chain application, *a requirement on the total number of parts* to be ordered from suppliers translates to a constraint on the sum of the number of parts available with each supplier (Example 2). As a result, queries must place constraints not only on part specifications but also the SUM of the parts available.
- When analyzing large data sets through aggregates [15], users often want to identify what input tuples produced outliers in aggregate values (e.g. select patients who had extremely high average cost). In this case, the user would like to place constraints on the AVG aggregate.

Example 1. *HighStyle Designers would like to run a Facebook¹ ad campaign to get more users to “like” their page. The campaign budget of \$10,000 will allow HighStyle to reach 1 million customers. Therefore, when the campaign manager, Alice, selects target users, she must not only constrain her search based on customer demographics but also based on the total number of customers who must be reached. This situation thus calls for an “Aggregation Constrained Query” (ACQ).*

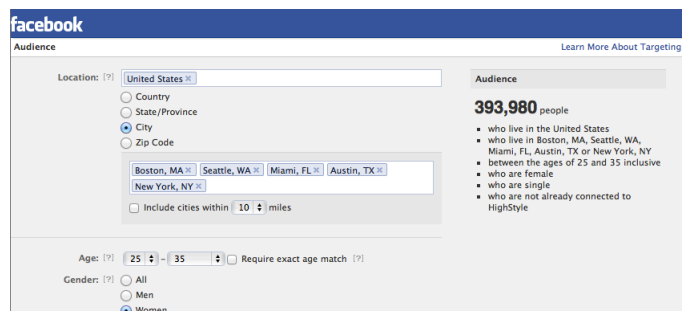

Figure 1: Facebook Ad Creation Interface: Allows specifying demographic criteria and view estimate of audience size.

Figure 1 shows the Facebook’s Advertising Interface² that allows campaign manager Alice to select target users for her ad. In terms of SQL, Alice has to run the following query:

```
Q1: SELECT * FROM Users
WHERE location in ('Boston', 'New York',
'Seattle', 'Miami', 'Austin') AND
(gender = 'Women') AND (25 <= age <= 35)
AND (education = 'CollegeGrad')
```

¹<http://www.facebook.com>

²<https://www.facebook.com/ads/create/>

```
AND (relationshipStatus = 'Single')
AND (interests IN {'Retail', 'Shopping'})
```

Need for Query Refinement. For Alice’s above query, Facebook estimates the reach to be 393,980 users, i.e. only 40% of the required 1 million users. While the results of query Q1 precisely satisfy Alice’s selection predicates, they are far from meeting her aggregate constraints. In fact, selection and aggregation constraints are orthogonal in most cases. As a result, we need to refine various query predicates in order to meet the aggregate constraints.

Current Approach. In existing systems Alice has to manually alter her criteria to encompass more users while ensuring that the semantics of her query are not altered. While some selection criteria (e.g. gender and shopping interest) may be fixed, Alice can try potentially infinite refinements of her predicates such as target consumers in additional cities; alter age range; relax relationship status; or any combination of the above. Repeatedly altering the original query and having its size estimated is not only inefficient for the backend, but the process is tedious and frustrating for Alice.

Desired User Experience. A much better user experience can be provided if Alice was allowed to specify her (1) demographic criteria (query), and (2) aggregate constraints, and the database engine can then execute variations of the input query such that the aggregate constraints are met. The output of such a search would be a set of refined queries that change Q1 as little as possible while meeting the aggregate constraints (in our case the audience size). Alice would then simply pick the query that best meets her selection criteria.

In this paper, we encode ACQs by introducing two SQL keywords **CONSTRAINT** and **NOREFINE**, where **CONSTRAINT** captures the aggregate constraint and **NOREFINE** specifies whether the predicate should not be refined. The encoded Query Q1 is:

```
Q1': SELECT * FROM Users
CONSTRAINT COUNT(*)=1M
WHERE location in ('Boston', 'New York',
'Seattle', 'Miami', 'Austin') AND
(gender = 'Women') NOREFINE AND (25 <=age<=35)
AND (education = 'CollegeGrad')
AND (relationshipStatus = 'Single') AND
(interests IN {'Retail', 'Shopping'}) NOREFINE;
```

Running Q1' will automatically generate alternate queries that produce 1M customers and alter Q1 as little as possible.

Example 2. *HybridCars Co. would like to place an order for 100,000 units of a burnished steel part having specific size, wholesale price less than \$1000, and from suppliers who have a low account balance. On the TPC-H benchmark, HybridCars runs query Q2 to find the suppliers with whom to place the order.*

```
Q2: SELECT * FROM supplier, part, partsupp
WHERE (s_suppkey = ps_suppkey) AND
(p_partkey = ps_partkey) AND
(s_acctbal < 2000)
AND (p_retailprice < 1000) AND (p_size = 10)
AND (p_type = 'SMALL BURNISHED STEEL')
```

As in Example 1, this situation calls for an ACQ as we would like to constrain the total number of available parts, i.e. *sum of the number of parts available per supplier* (i.e. $\text{SUM}(\text{ps_availqty})$) in addition the select predicates. We can encode the ACQ as Q2' to produce alternate refined queries. As before, the **NOREFINE** keyword associated with *p_type* and *p_size* indicate that these predicates cannot be altered.

```
Q2': SELECT * FROM supplier, part, partsupp
CONSTRAINT SUM(ps_availqty) >= 0.1M
WHERE (s_suppkey = ps_suppkey) NOREFINE AND
(p_partkey = ps_partkey) NOREFINE AND
(p_retailprice < 1000) AND (s_acctbal < 2000)
AND (p_size = 10) NOREFINE AND
(p_type = 'SMALL BURNISHED STEEL') NOREFINE
```

Building a system to execute ACQs is challenging because the number of possible refined queries is exponential in the number of predicates. Hence an exhaustive search of all possible queries is prohibitively expensive. Moreover even for aggregates such as **COUNT**, finding a query that meets its constraint is an NP-Hard problem [1]. In this paper, we limit ourselves to ACQs with numerical select and join predicates, and aggregates that satisfy the *optimal substructure* property (Section 2). Additionally, we focus on the problem of *expanding predicates* to meet constraints, rather than the inverse problem of shrinking queries returning too many tuples.

Contributions. We propose a technique to efficiently execute ACQs and our contributions are summarized as follows:

- We introduce and define semantics of a new class of queries called an **Aggregation Constrained Query** (ACQ). These special purpose queries are of value in real-world applications and are amenable to clever execution techniques.
- We propose a technique called **ACQUIRE** to execute ACQs via query refinement. **ACQUIRE** auto-generates alternative refined queries that minimize changes to the original query while meeting aggregate constraints.
- We combine the building blocks of breadth-first-search and dynamic programming in a novel way to elegantly and efficiently re-use query results. We call this *Incremental Aggregate Computation* (Section 5).
- We propose sensible default query refinement scoring and aggregate error functions. The design principle of **ACQUIRE** is general and therefore we allow user defined predicate refinement scoring and aggregate error functions. The functions used in this work are merely sensible defaults.
- Our experimental analysis on TPC-H dataset demonstrates that **ACQUIRE** consistently out-performs extensions to current techniques by up to 2 orders of magnitude. Moreover, queries recommended by **ACQUIRE** are on average closer to the original query by a factor of 2X more than the compared techniques (Section 8).

2. PRELIMINARIES

2.1 SQL extension for ACQs

We propose to capture ACQs by using two keywords: **CONSTRAINT** to describe the aggregate constraint and **NOREFINE** to indicate that a predicate should not be refined. By default, we assume that all predicates can be refined.

```
SELECT * FROM Table1, Table2 ...
CONSTRAINT AGG(attribute) Op X
WHERE Predicate1 AND Predicate2 ...
AND Predicate_i NOREFINE AND Predicate_j
AND ...Predicate_n NOREFINE
```

The aggregate constraint is of the form $AGG(attribute) Op X$, where AGG is a standard (COUNT, SUM, MIN, MAX, AVG) or user defined aggregate function, X is a positive number and Op is a comparison operator ($=, \leq, <, \geq, \text{and } >$). In this work, we focus on the problem of expanding predicates to meet constraints, rather than the inverse problem of shrinking queries returning too many tuples, we therefore limit the comparison operation to $=, \geq, \text{and } >$. Henceforth for illustrative purposes only we assume that the aggregate constraint has an equality condition.

2.2 Query Representation

In this work, we focus on queries with numeric select, project and join predicates of the form $Q = P_1 \wedge \dots \wedge P_d$, where P_i 's are predicates on relations $R_1 \dots R_k$. To illustrate consider query Q3 with one select and one join predicate.

Q3: SELECT * FROM A, B
WHERE A.x=B.x AND B.y < 50

For a given query Q , we divide each predicate P_i into two parts: the *predicate function* (P_i^F) and the *predicate interval* (P_i^I). P_i^F is a monotonic function on attributes of relations $R_1 \dots R_k$ while P_i^I denotes the interval of acceptable values for P_i^F , that is, $P_i^I = (min_i^I, max_i^I)$. To illustrate, if the minimum value of $B.y$ is 0, the predicate $(B.y < 50)$, in Q3 is decomposed into $P_i^F = B.y$ and $P_i^I = (0, 50)$. Range predicates like $(10 < B.y < 50)$ are rewritten as two one-sided predicates, $(B.y > 10) \wedge (B.y < 50)$. This enables the refinement of one or both sides of the range predicate. For equi-joins ($A.x = B.x$) and non-equi joins ($2 * A.x < 3 * B.x$), the form of P_i^I is unchanged; however, P_i^F takes the form $\Delta((P_i^F)_1, (P_i^F)_2)$, where $(P_i^F)_1$ and $(P_i^F)_2$ are separate predicate functions and Δ is the function measuring distance between them. Therefore, join predicate $A.x = B.x$ in Q3 is decomposed into $(P_i^F)_1 = A.x$ and $(P_i^F)_2 = B.x$. $P_i^I = (0, 0)$ signifies that values of the two functions must match exactly. For each predicate P_i , we also store a boolean value indicating whether the predicate can be refined. Recall that ACQ's contain an aggregate function that specifies the target value of an aggregate over the output result. We denote the target, or expected, aggregate value as A_{exp} and actual aggregate value returned by the query as A_{actual} .

2.3 Measuring Query Refinement Quality

We define a query refinement score to measure the change that has been made to the original query to obtain the refined query. A query $Q=(P_1 \wedge \dots \wedge P_d)$ is refined to Q' by refining one or more predicates $P_i \in Q$ to predicates $P_i' \in Q'$. The refinement of Q' along P_i , called the **predicate refinement score**, denoted as $PScore_i(Q, Q')$, is measured as the percent departure of $(P_i^I)'$ from P_i^I (Equation 1). Note that if $(P_i^I)_{min} = (P_i^I)_{max}$, $PScore_i(Q, Q') = 0$. For equality join predicates, the denominator is set to 100. Measuring relative change as opposed to absolute change in predicate intervals, compensates for the differing scales of query attributes. While percent refinement is the default predicate refinement metric used in this work, a user can override the metric with custom (monotonic) functions without changes to our algorithm. By computing the refinement score for each query predicate, a refined query Q' can be represented as a d-dimensional vector of predicate refinement scores, called the **predicate refinement vector** or $\overline{PScore}(Q, Q')$ (Equation 2).

$$PScore_i(Q, Q') =$$

$$\frac{|(P_i^I)_{min} - (P_i^I)'_{min}| + |(P_i^I)_{max} - (P_i^I)'_{max}|}{|(P_i^I)_{max} - (P_i^I)_{min}|} \cdot 100 \quad (1)$$

$$\overline{PScore}(Q, Q') = (PScore_1(Q, Q') \dots PScore_d(Q, Q')) \quad (2)$$

The **query refinement score** of Q' , denoted by $QScore(Q, Q')$ is defined as a monotonic function $f: \mathcal{R}^d \rightarrow \mathcal{R}$ used to measure the magnitude of $\overline{PScore}(Q, Q')$. We use the popular weighted vector p-norms [7] to calculate $QScore(Q, Q')$. Equation 3 shows the calculation of $QScore(Q, Q')$ using the default L_1 norm.

$$L_1: QScore(Q, Q') = \left(\sum_{i=1}^d PScore_i(Q, Q') \right) \quad (3)$$

Example 3. Consider the following refinement to Q3.

Q3': SELECT * FROM A, B
WHERE A.x = B.x AND B.y < 60

The refined query $Q3'$ expands the range of acceptable values for $B.y$ from $(0, 50)$ to $(0, 60)$. Therefore, $Q3'$ is represented as $\overline{PScore}(Q3, Q3') = (0, \frac{60-50}{50-0} \cdot 100)$ and has $QScore(Q3, Q3')=20$ for the L_1 norm.

2.4 Refining Join Predicates

The advantage of representing predicates as functions (P_i^F) and intervals (P_i^I), and defining refinement as the change in the predicate interval, is that join refinement can be expressed and operated on in the same way as select predicates. For instance, a query with $\overline{PScore}(Q3, Q3'') = (10, 20)$ indicates that the join predicate in Q3 has been refined by 10 to become $\|A.x - B.x\| \leq 10$ and that the $B.y$ predicate has been refined by 10 units. Thus, the algorithm can be applied unchanged for select as well as join queries.

2.5 Measuring Aggregate Error

To measure the difference between the expected aggregate value A_{exp} and the actual aggregate value A_{actual} , we use a relative error measure defined as:

$$Err_A = \frac{\|A_{exp} - A_{actual}\|}{A_{exp}} \quad (4)$$

This measure is appropriate for aggregates such as COUNT or AVG; however, a hinge-function that only penalizes errors on one side is appropriate for SUM, MIN and MAX.

$$Err_A = \begin{cases} (A_{exp} - A_{actual}) & \text{if } A_{exp} > A_{actual} \\ 0 & \text{otherwise} \end{cases}$$

2.6 Optimal Substructure Property

In this work, we limit ourselves to aggregate functions that either (a) have the **optimal substructure property** (OSP), or (b) can be broken down into functions that satisfy the OSP. Consider any two queries Q1 and Q2 such that all the results of query Q2 are also results of query Q1 (Q1 *contains* Q2). An aggregate is said to satisfy the OSP if the value of the aggregate for the results of Q1 can be computed without re-executing part or whole of the query Q2.

For instance, the COUNT aggregate is said to satisfy the OSP because given queries Q1 and Q2 as defined above, the value of COUNT for Q1 can be computed by adding the value of COUNT for Q2 to the value of COUNT for the query (Q1-Q2). SUM, MIN

and MAX similarly satisfy the OSP, and can be addressed by our technique. AVG, another common aggregate, can be broken down into two aggregates SUM and COUNT which have the optimal substructure property in turn, and therefore AVG can also be addressed by our technique. STDDEV, on the other hand, does not satisfy the OSP because even if the STDDEV for Q2's results are known, the results of Q2 must be re-analyzed to compute STDDEV for Q1.

2.7 Problem Definition

Given a query Q and a desired aggregate value A_{exp} , the problem of **Aggregation Constrained Query Execution** consists of refining Q to produce alternate queries Q' that produce the aggregate value A_{exp} while changing Q as little as possible. Formally, we can state it as follows:

DEFINITION 1. Given database \mathcal{D} , query Q , desired aggregate value A_{exp} , an aggregate error threshold δ , and refinement threshold γ , ACQ finds a set of refined queries Q' s.t. (a) the actual aggregate value for Q' , A_{actual} , satisfies: $Err_A \leq \delta$, and (b) $\|QScore(Q, Q_i) - QScore_{opt}\| \leq \gamma$, where $Q_i \in Q'$, $QScore_{opt} = \min \{QScore(Q, Q'_j) \mid \forall \text{ valid query refinements } Q'_j \text{ s.t. } (Err_A \leq \delta)\}$.

Since the problem of attaining the required aggregate value is NP-hard, we cannot provide formal guarantees about constraint (a) in Definition 1. However, as demonstrated in our experiments (Section 8), our algorithm ensures that the constraint is met practically every time. Our proximity-driven refinement technique guarantees that ACQUIRE will always meet constraint (b) in Definition 1.

We now turn our attention to evaluating these ACQs. As noted in the introduction, in this paper, our major focus is on queries that undershoot the aggregate constraint, however, we show in Section 7 how ACQUIRE can be extended to handle queries that overshoot the constraint. Furthermore, although we use COUNT as the aggregate of choice for all discussions, it is straightforward to support other aggregates with our technique and we note any changes to the algorithm that are required for doing so.

3. ACQUIRE: AN OVERVIEW

Given a query, the desired aggregate value, and acceptable result thresholds, ACQUIRE produces a set of refined queries that minimize changes to the original query but also satisfy the aggregate constraint. In formulating this set of refined queries, ACQUIRE adopts the strategy of *Expand* and *Explore* to iteratively *expand* the original query and to *explore* refined queries with respect to aggregate values. The *expand* phase ensures that refined queries satisfy the refinement threshold and that queries with smaller refinements are produced before those with larger refinements. Thus, once ACQUIRE finds a query satisfying the aggregate constraint, it need not examine queries with larger refinements. The *explore* phase on the other hand efficiently computes aggregate values for refined queries via an incremental aggregate computation algorithm. We delegate all actual query execution tasks to an *evaluation layer*, which in this case is Postgres. However, the evaluation layer is modular and can be replaced with other techniques such as estimation, and/or sampling. Our incremental aggregate computation algorithm exploits dependencies between refined queries and the optimal substructure property so that for each query, ACQUIRE must only execute a small sub-query and then simply use our recursive model to combine results from previous queries. Together, these two techniques ensure that once a query Q has been executed, any query Q' that *contains* Q will not have to re-execute Q . As a result, ACQUIRE can evaluate a large number of refined

queries at a cost that is a fraction of the execution time for a single query. Figure 2 shows the system architecture described above.

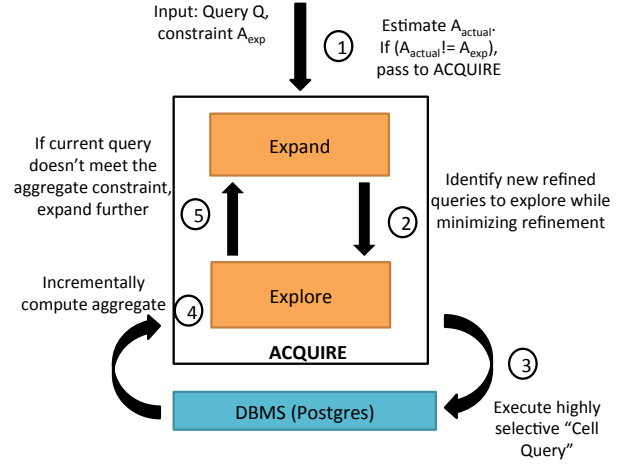

Figure 2: System Architecture of ACQUIRE

4. PHASE I: EXPAND

As described in the previous section, the *Expand* phase of ACQUIRE is responsible for iteratively generating refined queries that meet two criteria: (1) they satisfy the proximity threshold, and (2) their refinement scores ($QScore$ values) are greater or equal to the scores of previously generated queries.

Figure 3: Refined Space and Generation of Refined Queries

To meet the above query generation goals, ACQUIRE uses an abstraction called the **Refined Space** to represent all refined queries. Given an original query Q having d predicates, the *Refined Space*, denoted henceforth by $RS(Q)$, is a d -dimensional space, where the origin represents Q and the axes measure individual predicate refinement. To illustrate, consider a refined query Q' and assume that the L_1 norm is used to compute $QScore$. Q' would then be represented in $RS(Q)$ as (u_1, u_2, \dots, u_d) where $u_i = (PScore_i(Q, Q')) \forall i = 1, \dots, d$, making $QScore(Q, Q') = (\sum_{i=1}^d u_i)$. Conversely, every point in the refined space (u_1, u_2, \dots, u_d) corresponds to some query Q' with $PScore_i(Q, Q') = u_i$. Therefore, any d -dimensional hyper-rectangle on $RS(Q)$ also corresponds to a query.

ACQUIRE divides $RS(Q)$ into a multi-dimensional grid with step-size $\frac{\gamma}{d}$ to avoid an exhaustive search of $RS(Q)$ and to stay within the proximity threshold, as illustrated by Theorem 1. Each query on the multi-dimensional grid is called a *grid query*.

Theorem 1. Suppose the original query is Q and Q_{opt} is the optimal query meeting the aggregate constraint and having minimum refinement. Let $RS(Q)$ be a multi-dimensional grid with step-size on each axis equal to $\frac{\gamma}{d}$. Then at least one refined query Q' lying on the $RS(Q)$ grid will satisfy the proximity constraint w.r.t. to Q_{opt} .

Proof: Let $Q_{opt} = \{u_1, u_2, \dots, u_d\}$ lie in some grid cell G in $RS(Q)$. Since the refined space grid has step-size $\frac{\gamma}{d}$, any query $Q' = \{u'_1, u'_2, \dots, u'_d\}$ on G satisfies:

$$|u_1^p - u_1'^p| + |u_2^p - u_2'^p| + \dots + |u_d^p - u_d'^p| \leq \frac{\gamma}{d} \cdot d = \gamma$$

$$\Rightarrow |(u_1^p + u_2^p + \dots + u_d^p) - (u_1'^p + u_2'^p + \dots + u_d'^p)| \leq \gamma$$

$$\Rightarrow |QScore(Q_{opt}, Q)^p - QScore(Q', Q)^p| \leq \gamma$$

$$\Rightarrow QScore(Q_{opt}, Q)^p - QScore(Q', Q)^p \leq \gamma$$

(assume $QScore(Q_{opt}, Q)^p \geq QScore(Q', Q)^p$)

$$\Rightarrow (QScore(Q_{opt}, Q) - QScore(Q', Q)) \cdot (QScore(Q_{opt}, Q)^{p-1} + QScore(Q_{opt}, Q)^{p-2} \cdot QScore(Q', Q) + \dots + QScore(Q', Q)^{p-1}) \leq \gamma$$

$$\Rightarrow (QScore(Q_{opt}, Q) - QScore(Q', Q)) \leq \gamma (\gamma > 1) \quad \blacksquare$$

Figure 3 depicts the refined space abstraction for query Q3 assuming $\gamma = 10$. Since Q3 has two predicates, step-size=5 and $RS(Q3)$ is a 2-dimensional space with the axes respectively measuring the refinements along the select and join predicates. A refined query like Q3' having $PScore(Q3, Q3') = (0, 20)$ is represented as (0, 4) in $RS(Q3)$.

The second goal of the *Expand* phase is to generate refined queries in order of increasing refinement. ACQUIRE achieves this goal by producing queries close to the origin in $RS(Q)$ before those far from it. In particular, the *Expand* phase uses breadth-first search to generate refined queries in layers where queries in a given *query-layer* have the same $QScore$. Consequently, for all L_p norms except L_∞ , query-layers take the form of d-dimensional planes corresponding to $QScore = k \Rightarrow QScore^p = k^p \Rightarrow (\sum_{i=1}^d u_i^p) = k^p$. For L_∞ , however, query-layers are L-shaped and intersect each axis at k^p . Figure 3 shows query-layers for Q3 assuming the L_1 and L_∞ norms. Beginning with the query-layer with refinement 0, ACQUIRE generates all grid queries in the current query-layer. If no query from the current layer satisfies the aggregate constraint, ACQUIRE proceeds to the next query-layer having $QScore$ increased by $\frac{\gamma}{d}$. Since this iterative expansion model examines queries in order of increasing refinement, ACQUIRE can stop immediately after a query is found to meet the required constraint, thus reducing the number of queries examined by ACQUIRE. Algorithms 1 and 2 respectively describe the pseudo code for generating queries using the L_p and L_∞ norms. The L_p algorithm generates query-layers using a breadth-first search while the L_∞ norm sequentially enumerates queries in the given layer.

Algorithm 1 GetNextQuery(Queue queryQue)

```

1: int[]  $Q_{curr} = queryQue.Pop()$  //Indexed from 1
2: for  $i = 1, \dots, d$  do
3:    $Q_{next} \leftarrow GetNextNeighbor(i)$  //Increment i-th dimension
    of  $Q_{curr}$  by stepsize
4:   if ( $!queryQue.Contains(Q_{next})$ ) then
5:      $queryQue.Push(Q_{next})$ 
6: return  $Q_{curr}$ 

```

Algorithm 2 GetNextQuery(Queue queryQue, int currRef)

```

1: if ( $!queryQue.Empty()$ ) then
2:   return  $queryQue.Pop()$ 
3: else
4:   Query  $Q_{new} = 0$ 
5:   for  $i = 1, \dots, d$  do
6:      $Q_{new}[i] = currRef$ ;  $queryQue.Push(Q_{new})$ 
7:   while  $Q_{new} \neq null$  do
8:     IncrementQuery( $Q_{new}$ ,  $i$ ,  $currRef$ ) // enumerate
    queries with i-th dim fixed at currRef and others < currRef
9:      $queryQue.Push(Q_{new})$ 

```

Theorem 2. A grid query Q'_i with $QScore(Q, Q'_i) = k$ is investigated after all grid queries with $QScore(Q, Q'_i) = (k - 1)$ have been investigated.

Proof: Consider the refined space to be a directed graph with the origin as the root and every grid query as a node. Every grid query is connected to d queries obtained by incrementing one dimension by the unit step-size. These connections form the graph's edges. Then *GetNextQuery* for the L_p norm performs a breadth-first search on the refined space grid, guaranteeing that all queries at distance $k - 1$ from the root are investigated before those at distance k . The result is trivially true for L_∞ norm since our algorithm explicitly generates queries in each query layer. \blacksquare

Time Complexity. The worst case complexity of the *Expand* phase is $\mathcal{O}(V + E)$ where V is maximum number of refined queries in the grid and $|E| = d \cdot |V|$.

5. PHASE II: EXPLORE

The *Explore* phase of ACQUIRE is responsible for efficiently computing the aggregate values of queries produced in the *Expand* phase. For this purpose, we introduce a light-weight query execution methodology based on a novel, efficient incremental query execution algorithm that exploits dependencies between refined queries using a specialized recursive model. For each query, our model requires execution of only one sub-query and computes the overall aggregate by intelligently combining partial results from previous queries. ACQUIRE guarantees that a query is executed at most once, irrespective of how many queries contains it.

5.1 Incremental Aggregate Computation

The principle underlying our query execution algorithm is that refined queries often share results. Therefore, once a query result has been evaluated it must never be re-evaluated for any other query.

Query Containment. A refined query $Q' = (u'_1, u'_2, \dots, u'_d)$ is said to be *contained* within another refined query $Q'' = (u''_1, u''_2, \dots, u''_d)$ if $(u'_i \leq u''_i) \forall i = 1 \dots d$.

Theorem 3. If refined query Q' is contained within refined query Q'' : (1) all results of Q' also satisfies Q'' . (2) Q' is guaranteed to be generated before Q'' in the *Expand* phase.

Proof: Let tuple τ satisfy Q' . (1) By Equation 2:
 $PScore_i(\tau, Q) \leq PScore_i(Q', Q) \forall i = 1, \dots, d$
 $\Rightarrow PScore_i(\tau, Q)^p \leq PScore_i(Q', Q)^p = u_i'^p \forall i = 1, \dots, d$
 $(PScore \geq 0)$
 $\Rightarrow PScore_i(\tau, Q)^p \leq u_i''^p$
 $\Rightarrow PScore_i(\tau, Q) \leq PScore_i(Q'', Q)$.

Consequently, all the query results of Q' also satisfy Q'' . For

Figure 4: Sub-queries of a 2-D query

(2), from the definition of contained queries, $QScore(Q', Q) \leq QScore(Q'', Q)$. Therefore, by Theorem 2, the *Expand* phase will produce Q' before Q'' . ■

Since all contained queries are produced and executed before those containing them, ACQUIRE can extensively use previously-generated query results. In particular, ACQUIRE exploits the concept of query containment by constructing contained queries, called *sub-queries* henceforth, that are used as units of query execution and result sharing. We now describe the sub-queries used.

5.1.1 Query Decomposition

Consider query Q' with d predicates, represented as point (u'_1, \dots, u'_d) in the refined space. In addition to Q' , ACQUIRE defines d specialized sub-queries contained within it, giving $d + 1$ queries in all. Figure 4 shows these queries for a 2-predicate query. The first sub-query (A) corresponds to the unit square in $RS(Q)$ with its upper-right corner at $Q' = (u'_1, u'_2)$, the second sub-query (B) corresponds to a unit-width rectangle in $RS(Q)$ with Q' at its upper-right corner, and the third sub-query is the entire query (C). Similarly, for a 3-predicate query as in Figure 5, the first sub-query (A) is the unit cube, the second (B) is a unit length and width parallelepiped, the third (C) is a unit width parallelepiped, and the fourth (D) is the entire query sub-query. For ease of exposition, we refer to the first sub-query as **cell**, the second as **pillar**, the third as **wall**, and the fourth as **block**, respectively.

In a d -dimensional refined space, the $d + 1$ sub-queries, called O_1, O_2, \dots, O_{d+1} , can be formally defined as shown in Equations 5-8. All $d + 1$ sub-queries have the same upper bound ($Q' = (u'_1, \dots, u'_d)$), but different lower bounds. For instance, the cell sub-query O_1 has a lower bound which is a unit length away from (u'_1, \dots, u'_d) on all dimensions (Equation 5). The cell sub-query corresponds to the cell in the refined space grid having (u'_1, \dots, u'_d) as its upper bound. Similarly, the pillar sub-query has a lower bound with the first dimension equal to 0 and all remaining dimensions j ($j = 2, \dots, d$) unit length away from u'_j (Equation 6). In general, the lower bound of the j^{th} sub-query O_j is $(0, \dots, 0, u'_j - 1, \dots, u'_d - 1)$. For simplicity, we will refer to an sub-query O_i corresponding to query (u'_1, \dots, u'_d) as $O_i(u'_1, \dots, u'_d)$.

$$O_1 = ((u'_1 - 1, \dots, u'_d - 1), (u'_1, \dots, u'_d)) \quad (5)$$

$$O_2 = ((0, u'_2 - 1, \dots, u'_d - 1), (u'_1, \dots, u'_d)) \quad (6)$$

$$O_j = ((0, 0, \dots, 0, u'_j - 1, \dots, u'_d - 1), (u'_1, \dots, u'_d)) \quad (7)$$

$$O_{d+1} = ((0, \dots, 0), (u'_1, \dots, u'_d)) \quad (8)$$

By decomposing a query into the sub-queries defined above, we can reuse previously obtained results. To illustrate, consider Figure 6.a where the 2-D query is decomposed into 3 sub-queries. We observe that sub-query A is the *Cell* (u'_1, u'_2) , B is the *Pillar* $(u'_1, u'_2 - 1)$, and C is the *Wall* $(u'_1 - 1, u'_2)$. Similarly, Figure 6.b shows the decomposition of a 3-predicate query into the four sub-queries A, B, C and D which are respectively the *Cell* (u'_1, u'_2, u'_3) , the

Figure 6: Query Decomposition: (a) 2-D (b) 3-D

Pillar $(u'_1 - 1, u'_2, u'_3)$, the *Wall* $(u'_1, u'_2 - 1, u'_3)$, and the *Block* $(u'_1, u'_2, u'_3 - 1)$. In general, a d -predicate query can be decomposed into the previously defined $(d + 1)$ sub-queries:

2 – predicate Query : (9)

$$O_3(u'_1, u'_2) = O_1(u'_1, u'_2) + O_2(u'_1 - 1, u'_2) + O_3(u'_1, u'_2 - 1)$$

3 – predicate Query : (10)

$$O_4(u'_1, u'_2, u'_3) = O_1(u'_1, u'_2, u'_3) + O_2(u'_1 - 1, u'_3, u'_3) + O_3(u'_1, u'_2 - 1, u'_3) + O_4(u'_1, u'_2, u'_3 - 1)$$

d – predicate Query : (11)

$$O_{d+1}(u'_1, u'_2, \dots, u'_d) = O_1(u'_1, u'_2, \dots, u'_d) + O_2(u'_1 - 1, u'_2, \dots, u'_d) + O_3(u'_1, u'_2 - 1, u'_3, \dots, u'_d) + \dots + O_{d+1}(u'_1, u'_2, \dots, u'_d - 1)$$

Thus, if the aggregates for the $(d + 1)$ sub-queries have been pre-computed, the aggregate of query Q' is the mere addition¹ of these sub-aggregates. We must store only the aggregate *values* for the $d + 1$ sub-queries. The corresponding result tuples can either be stored in main memory or paged to disk. The above sub-query decomposition also leads to two crucial observations: (1) **The only part of a query unique to itself is the cell**; all remaining parts of the sub-query are shared with other queries. (2) **The $d + 1$ sub-queries defined above belong to queries completely contained in Q'** . Therefore, Theorem 3 guarantees that these queries would have been produced and hence executed before investigating Q' . As a consequence, ACQUIRE must only execute the cell sub-query and can directly reuse aggregates of the remaining sub-queries.

5.1.2 Recursive Aggregate Computation

Query decomposition assumes that the aggregates for the $d + 1$ sub-queries have already been computed. But independently determining aggregates of these sub-queries is redundant. Instead, we present a recursive strategy to calculate the aggregates of the sub-queries in constant time. Reconsider Figure 6 focusing now on the relationship between sub-queries. We observe that for 2-predicate sub-queries (Figure 6.a) the *Pillar* (u'_1, u'_2) is equivalent to *Cell* (u'_1, u'_2) and *Pillar* $(u'_1 - 1, u'_2)$ combined. Similarly, the *Wall* (u'_1, u'_2) , which is the entire query is equal to the sum of *Pillar* (u'_1, u'_2) and *Wall* $(u'_1, u'_2 - 1)$. For the 3-predicate query, in Figure 6.b, we have three similar recurrences as shown below.

¹For aggregates like MIN/MAX, addition is replaced by the corresponding MIN/MAX function, while AVERAGE = SUM/COUNT. SUM and COUNT aggregates are computed and stored separately. AVERAGE is computed from these values as required.

Figure 5: Sub-queries of a 3-predicate query

2 – Recurrences :

$$Pillar(u'_1, u'_2) = Cell(u'_1, u'_2) + Pillar(u'_1 - 1, u'_2) \quad (12)$$

$$Wall(u'_1, u'_2) = Pillar(u'_1, u'_2) + Wall(u'_1, u'_2 - 1) \quad (13)$$

3 – Recurrences :

$$Pillar(u'_1, u'_2, u'_3) = Cell(u'_1, u'_2, u'_3) + Pillar(u'_1 - 1, u'_2, u'_3) \quad (14)$$

$$Wall(u'_1, u'_2, u'_3) = Pillar(u'_1, u'_2, u'_3) + Wall(u'_1, u'_2 - 1, u'_3) \quad (15)$$

$$Block(u'_1, u'_2, u'_3) = Wall(u'_1, u'_2, u'_3) + Block(u'_1, u'_2, u'_3 - 1) \quad (16)$$

In general, this recursion for a d-predicate query is:

$$O_i(u'_1, \dots, u'_d) = O_{i-1}(u'_1, \dots, u'_d) + O_i(u'_1, u'_2, \dots, u'_{i-1} - 1, \dots, u'_d) \text{ where } i = 2, \dots, d+1 \quad (17)$$

Since the sub-query O_1 has no recurrences, its aggregate must be computed by executing the query. However, once the aggregate of O_1 is determined, it takes d (constant) steps to calculate the total aggregate for query Q' .

5.1.3 Aggregate Computation Algorithm

Algorithm 3 takes as input the query $Q'(u'_1, \dots, u'_d)$ being investigated and produces its aggregate. For this, Algorithm 3 first computes the aggregate of the $Cell(u'_1, \dots, u'_d)$, and then iteratively applies the recurrence in Equation 17 to compute aggregates of the remaining sub-queries. The function `ExecuteCellQuery` is used to compute the aggregate over a single input cell by issuing a query to the evaluation layer.

Algorithm 3 ComputeAggregate(Query Q_{curr} , int d)

```

1: int[d + 1]  $A_{curr}$  // All arrays are indexed from 1
2:  $A_{curr}[1] = \text{ExecuteCellQuery}(Q_{curr})$ 
3: for  $i = 2, \dots, d + 1$  do
4:    $Q_{prev} \leftarrow \text{GetPreviousNeighbour}(i-1)$  // decrement the  $(i - 1)^{th}$  dimension of  $Q_{curr}$  by stepsize
5:   int[]  $A_{prev} = \text{GetAllAggregates}(Q_{prev})$ 
6:    $A_{curr}[i] = A_{curr}[i - 1] + A_{prev}[i]$ 
7: StoreAllAggregates( $Q_{curr}, A_{curr}$ )
8: return  $A_{curr}[d + 1]$ 
```

6. PUTTING IT ALL TOGETHER

Algorithm 4 presents the pseudo code for the ACQUIRE framework. Given an initial query Q and the refinement threshold γ , ACQUIRE begins to iteratively *Expand* and *Explore* refined queries,

starting at the origin of the refined space and sequentially traversing queries in subsequent layers. For each refined query, ACQUIRE calculates the aggregate using the Incremental Aggregate Computation technique described in Algorithm 3. Once the aggregate value A_{actual} has been determined, it is compared to A_{exp} . If the aggregate is within the error threshold δ , the query is stored in the answer list (\mathcal{A}). In this case, query search terminates with the exploration of all queries in the current layer, i.e., all alternate queries with the same refinement score. If all queries in a layer undershoot the constraint by more than δ , ACQUIRE explores the next higher layer. Lastly, if any query overshoots the expected aggregate value by more than δ , we repartition the cell corresponding to the given query and examine queries lying within. We repeat the repartitioning process for b iterations, where b is a tunable parameter. If, at the end of repartitioning, no query is found to satisfy the aggregate constraint, ACQUIRE returns the query attaining the closest aggregate value.

Algorithm 4 ACQUIRE(Query $Q_{original}$, double A_{exp} , int δ , double γ)

```

1:  $\mathcal{A} = []$  // Set of refined Queries
2: Queue  $queryQueue = []$  // Data structure for traversal
3:  $d \leftarrow$  Flexible predicates in  $Q_{original}$ 
4: int[d]  $Q_{curr} = \{0, \dots, 0\}$  // Origin represents  $Q_{original}$ 
5:  $queryQueue.push(Q_{curr})$ 
6: int  $minRefLayer = \text{MAX\_INTEGER\_VALUE}$ 
7: int  $currRefLayer = 0$ 
8: while ( $currRefLayer \leq minRefLayer$ ) do
9:   double  $A_{actual} = \text{ComputeAggregate}(Q_{curr}, d)$  // Algorithm 3
10:  if ( $|A_{exp} - A_{actual}| \leq \delta$ ) then
11:     $\mathcal{A}.add(Q_{curr})$ 
12:     $minRefLayer = currRefLayer$ 
13:  else if ( $A_{exp} > A_{actual}$ ) then
14:     $\mathcal{A}.add(\text{Repartition}(Q_{curr}))$ 
15:     $Q_{curr} = \text{GetNextQuery}(queryQueue)$  // Algorithm 1
16:     $currRefLayer = \text{QScore}(Q_{curr})$ 
17: return  $\mathcal{A}$ 
```

7. EXTENSIONS

In this section, we present extensions to the framework that accommodates some of the limitations of our approach.

7.1 Preferences in Refinement

Along with the NOREFINE keyword used to identify and preserve rigid constraints, ACQUIRE allows users to set preferences

on which predicates should be refined. This can be easily done by specifying a L_{W_p} norm which sets appropriate weights on various predicates. Similarly, users can also supply maximum refinement limits on predicates. While we provide several avenues for user control, user intervention is not required and each tunable parameter is provided an appropriate default setting.

7.2 Contracting Queries With Too Many Results

ACQUIRE with minor modifications handles queries that generate *too many results*. This is achieved by constructing a query Q'_{min} with each predicate of the original query Q set to its minimum value. Since Q'_{min} will produce too few results, we can now construct a refined space bounded by Q and Q'_{min} . ACQUIRE now traverses the refined space to find queries that meet the cardinality constraint, this time minimizing refinement with respect to Q instead of Q'_{min} .

Figure 7: Ontology for Categorical Data

7.3 Non-numeric Predicates

The focus of this work is to handle numeric predicates. Measuring refinement distance between categorical data points is in itself a challenging problem, requiring the analysis of taxonomy information. However, ACQUIRE can be extended to support categorical predicates by plugging in the appropriate means for measuring the *distance between any two categorical values*. For example, Figure 7 depicts sample ontology trees related to *food* preferences and *location*. The refinement distance between the original query desiring places that serve *Gyro* to restaurants that have any *Mediterranean cuisine* may be defined based on the relative depths of the two nodes. In general, the roll-up operation on an ontology tree corresponds to making the predicate less selective, i.e., relaxation. While the drill down operation translates to query contraction. Given this meta-information from the ontology tree and a distance metric, the ACQUIRE framework can be used to refine categorical predicates.

7.4 Exploiting Indexes and Data Distribution

The algorithms discussed so far make no assumptions about the underlying data distribution or presence of indexes on the data. Moreover, experiments in Section 8 indicate that ACQUIRE is already 2 orders of magnitude faster than the state-of-the-art techniques. However, if required, we can further boost the efficiency of ACQUIRE by employing a specialized bitmap-like index structure on the tables. To construct this index, we divide each attribute dimension into equi-width parts and create a multi-dimensional grid on the table. We then examine the records in the table to determine which grid cell each record belongs to. In our index, each cell is assigned a corresponding bit, which is set to 1 if the cell contains some tuple and 0 otherwise (storing the number of tuples may be easier for keeping the index up-to-date but requires more space). Once constructed, this simple index structure can be used

in the *Explore* phase to determine if a given cell query is empty without actually executing the query. If the query is found to be empty, we can safely skip it and proceed to the next, thus avoiding unnecessary query execution costs.

8. EXPERIMENTAL EVALUATION

8.1 System Implementation

The ACQUIRE framework is built on top of Postgres. ACQUIRE sits outside the DBMS where it performs the tasks of exploring the refinement space, formulating queries and applying our aggregate computation algorithm. To make ACQUIRE portable across multiple database systems, and to aid in proper comparison with competing techniques, all query execution tasks are delegated to the DBMS. We similarly implemented the compared techniques on top of Postgres.

8.2 Alternative Techniques

We compare ACQUIRE to three extensions of existing techniques that address the ACQ problem to varying degrees. First, we compare it to Top-k which, although unable to produce *refined queries*, is suited to ranking tuples in order of refinement. While it is straightforward to translate a COUNT constraint to Top-k, translating other aggregate constraints (e.g. AVERAGE) is difficult if not impossible. As a result, we only study Top-k ranking for COUNT constraints. We use existing DBMS capabilities of ORDER BY and LIMIT to implement Top-k, as demonstrated on generic queries (Q and corresponding Top-k- Q) below.

```
Q = SELECT COUNT(*) from table1
    WHERE x <= 10 and y <= 20;
```

```
Top-k-Q = SELECT * FROM table1 ORDER BY
(case when (x <= 10) then 0
else (x - 10) / (x.max - x.min)) +
(case when (y <= 20) then 0
else (y - 20) / (y.max - y.min)) LIMIT A_exp
```

We also compare ACQUIRE to the TQGen [11] and a simple binary search (BinSearch) technique [11]. Our experiments uses the TQGen parameters reported in [11]. To allow for uniform comparisons across all methods, we do not employ sampling techniques for TQGen. However, our experiments demonstrate that our results hold even for small sample-size datasets (see Figure 10.a). The final point to note is that, unlike ACQUIRE, (a) none of the above techniques addresses aggregates other than COUNT, and (b) even for COUNT, none of the above techniques are capable of refining join predicates.

8.3 Methodology

To study the robustness of ACQUIRE we vary (1) *dimensionality* of refinement space, i.e., number of refinable predicates, and combination of attributes in these predicates, (2) *magnitude of aggregate value discrepancy*, i.e., ratio A_{actual}/A_{exp} between the actual aggregate value and the desired aggregate value, (3) *dataset size*, (4) *aggregate types*, and (5) *data distributions*. To study the efficiency gained by the ACQUIRE system, we evaluated the net decrease in query execution time for various data sizes and dimensionality. Finally, we evaluated the performance of ACQUIRE under various settings of refinement and aggregate thresholds as well as presence of join refinement. For each experimental setting, we measure the time needed to return the set of refined queries, Q_F , amount of refinement (refinement score), and relative aggregate error = Err_A .

Figure 8: Performance Comparison Under Varying Aggregate Ratios: ACQUIRE, Top-k, TQGen and BinSearch

All algorithms were implemented in Java. Measurements were obtained on AMD 2.6GHz Dual Core CPUs, and Java heap of 2GB. We utilized the TPC-H datasets of varying sizes (1K - 10M tuples). Since the standard TPC-H data is uniformly distributed (i.e., $Z = 0$), we used [3] to also generate skewed data with $Z = 1$. Our test queries are TPC-H queries which have been adapted to include only numeric range and join predicates. Query Q2 (in Example 2) provides skeleton query that was used to evaluate the SUM aggregate. For each dataset, query, and ACQUIRE settings, we define the original aggregate A_{actual} and the aggregate ratio $\frac{A_{actual}}{A_{exp}}$.

8.4 Performance Comparisons

8.4.1 Effect of $\frac{A_{actual}}{A_{exp}}$ Ratio

We first examine the effect of aggregate ratio, $\frac{A_{actual}}{A_{exp}}$, on the execution time, error rate and refinement scores. A small $\frac{A_{actual}}{A_{exp}}$ ratio implies that the original query is highly selective and needs large refinements, while a large $\frac{A_{actual}}{A_{exp}}$ implies that the original query is close to the desired query and needs only small refinements. These experiments were carried out on a 1 million tuple dataset and a query with 3 flexible predicates. The aggregate ratio was varied between 0.1 - 0.9.

As shown in Figure 8.a, the execution time for ACQUIRE increases with decreasing expansion ratio, i.e., the greater the need to expand the query, longer it takes for ACQUIRE to reach the required aggregate ratio. While Top-k requires the same execution time (the ranking function is unchanged and all records need to be sorted), its execution time however is on average 3.7X more than ACQUIRE. TQGen and BinSearch both need to explore the same number of queries each time and hence their execution time remains constant. ACQUIRE does consistently as well as all the other methods, and is on average 2X faster than BinSearch and 2 orders of magnitude faster than TQGen (Y-axis is in log scale). Although BinSearch shows promise with respect to execution time, we show next that it is not robust with respect to aggregate errors.

Figure 8.b shows the relative error (average relative error for BinSearch) for each of the queries with changing aggregate ratio. We do not compare Top-k because a Top-k query explicitly specifies

the number of tuples to return and hence has no aggregate error by definition. The BinSearch line in the graph shows that BinSearch is extremely unstable and has high variance in aggregate errors. The underlying reason is that BinSearch is very sensitive to the order in which predicates are refined; even a single change to the order can change the error by a factor of 100. To illustrate, one ordering of predicate refinement in BinSearch produces a refinement error of 0.19 or 20% whereas another ordering produces an error of 0.002 or 0.2%. Attempting to refine the query by attempting all orderings of predicates is computationally expensive. ACQUIRE, on the other hand, not only produces queries consistently within the threshold ($\delta = 0.05$), but also does so efficiently. TQGen, in fact, produces lower error rates than ACQUIRE. However, this reduction comes at the cost of a 100X increase in execution time. Since both error rates are acceptable, we prefer ACQUIRE. Lastly, in Figure 8.c we compare the refinement scores obtained by each method. We see that the refinement score for queries generated by other methods are 2-3X larger than those from ACQUIRE.

8.4.2 Effects of Dimensionality

Next, we discuss the effects of increasing dimensionality, i.e. increase in the number of query predicates. We used the same dataset as before, used expansion ratio = 0.3 and varied the number of predicates in the query. In execution time, we see the same trend as before where the execution time increases with increasing dimensionality of the query. However, for ACQUIRE, the increase is largely linear and not exponential. For Top-k, the execution time remains largely constant since only the ranking function changes. For TQGen, we see an exponential increase in the execution time (as number of queries executed is exponential in number of dimensions) with the method taking 500X more time than ACQUIRE for high dimensional queries. Thus, ACQUIRE is a much better alternative to the state-of-the-art on queries of varying dimensions. Figure 9.b once again demonstrates that BinSearch is extremely unstable with respect to aggregate error. While some queries obtain an error rate of 0.6%, some obtain an unacceptable error rate of 45%. This large variance in error values produced by BinSearch indicates that the method is unpredictable and not-robust. As a result, it cannot guarantee any threshold on the error rate.

Figure 9: Performance Comparison Under Varying Number of Predicates Ratios: ACQUIRE vs. Top-k vs. TQGen vs. BinSearch

Figure 10: Performance Comparison Under Varying (a) Table Size, (b) Refinement Threshold and (c) Cardinality Threshold

In Figure 8.c exemplifies the trends in query refinement score seen with all methods. The refinement scores of ACQUIRE are consistently the lowest across all methods – meaning fewer changes to the original user query and therefore more desirable. Top-k produces higher refinement than ACQUIRE. This figure also shows that TQGen and BinSearch can have high variance in refinement scores. Since the goal of these techniques is only to meet the aggregate constraint and not to minimize refinement, this is expected. BinSearch queries have, on average, 4.8X more refinement than ACQUIRE queries.

8.4.3 Varying Table Size

For datasets of varying size, beginning with a 1k-tuple dataset (to mimic a sample based approach) to a 1M-tuple dataset. As shown in Figure 10.a the execution time for ACQUIRE and all compared techniques increases proportionally to the size of the dataset. Relative error and refinement scores show the same trends as before.

8.4.4 Effect of Varying Data Distributions

To study the robustness of our method, we re-ran experiments on data with Zipfian skew = 1. Trends in results were same as above.

8.4.5 ACQUIRE Parameter Studies

In Figure 10.a and Figure 10.c, we report the performance of ACQUIRE with respect to its internal parameters, namely the aggregate threshold, the number of steps in the grid and the depth of the search. As expected, a stringent cardinality and refinement threshold produces proportional increases in the ACQUIRE execution time as more queries need to be explored.

8.4.6 Varying Aggregate Types

ACQUIRE framework is general and can be applied to different types of aggregates satisfying the optimal substructure from Section 2.6. We tested the technique for other aggregates too. Figure 11 shows the results for the SUM, COUNT and MAX aggregates. We omit MIN since this can be written as the MAX(-1 *

Figure 11: ACQUIRE's Performance on Different Aggregates

attribute). We find that ACQUIRE successfully minimizes refinement and reaches the aggregate thresholds in all the above aggregates.

8.5 Summary of Experimental Conclusions

1. ACQUIRE is consistently 2 orders of magnitude faster than TQGen and on average 2X faster than *BinSearch*.
2. In all experimental conditions, ACQUIRE's aggregate error is well below the aggregate error threshold. In contrast, *BinSearch* has very high variance in error rates, reaching up to 45% of the expected aggregate value.
3. Although, Top-k can be efficient at small-sized datasets, it quickly becomes inefficient as data size increases. In general Top-k is about 3.7 times slower than ACQUIRE.
4. ACQUIRE generates queries that on average have 2X better refinement scores than a query produced by either TQGen or *BinSearch*.

9. RELATED WORK

In this section, we discuss two areas of related work namely, (1) *set-based queries* [6, 5, 16, 14, 13] and (2) solving the *empty result problem* [9, 1, 11]. Existing set-based query evaluation techniques

differ from our work fundamentally because they are solving a different problem than the one addressed in this work. For instance, techniques proposed in [13] address the problem of recommending "satellite items" (e.g., car charger, case) for a given item that the customer is currently shopping for (e.g. smart phones). Alternatively, [16, 5] solve the generalized Knapsack problem [6] of making composite recommendations of a set of items. That is, recommend the Top-k sets of items with the total cost below a given budget and preferring the set with higher ratings. In contrast, [14] focused on finding users (e.g. tourists) sets of results (e.g. a set of places of interest) given a set of constraints (e.g. budget). This is identical to the current behavior of the Facebook Ad Creation Interface [4]. However, this approach is less than desirable (as described in Section 1) as it would force Alice to go through hundreds of iterations to find a meaningful query that meet the aggregate constraints. To summarize, techniques for set-based queries focus on returning tuples or sets of tuples that meet a constraint. In large scale database systems since the users are mostly unfamiliar with the characteristics of the underlying data, they usually construct queries that are either too strict or too broad [9]. In such scenarios, execution techniques designed for set-based queries could potentially return no results or all tuples in the database.

To the best of our knowledge, we are the first work to address the question of recommending refined user queries that meets their aggregate constraints. Existing query refinement techniques can be classified into two categories namely, (1) *tuple-oriented approaches*, and (2) *query-oriented approaches*. Table I summarizes the key related work, and whether they support all aggregate constraints and / or a proximity criteria.

Techniques	Aggregates Supported	Proximity	Card.	Query
Tuple-Oriented: Skyline [8], Top-k [2]	COUNT	✓	✓	
Query-Oriented: BinSearch [11], IQR [10]	COUNT			✓
Query-Oriented: TQGen [11], Hill-Climbing [1]	COUNT		✓	✓
ACQUIRE	COUNT, SUM, MIN, MAX, AVG, UDA ²	✓	✓	✓

Table 1: Summary of the Related Work

Tuple-Oriented Techniques. Result refinement techniques [12, 8] focus only on generating the required number of results and ignore the problem of generating refined queries that explain how the result tuples were selected. The refinement criteria are crucial in scientific and business applications. Similarly Top-k algorithms, such as [2], while useful in many instances cannot correctly address the ACQ problem since they can only handle COUNT aggregates. To illustrate, consider a query that selects patients based on income, blood pressure, and the amount of weekly exercise. A Top-k based approach will obtain the required number of patients, but these patients will likely be skewed in certain predicate dimensions and will not be representative of the population. Thus pure Top-k and its variations are inadequate to address the ACQ problem; clearly demonstrated in our experiments (see Section 8).

Query-Oriented Approach. More recently in the context of database testing [1, 11, 10] have started to focus on the problem of

²User Defined Aggregates that either satisfy the optimal substructure property (OSP) or can be broken into functions that satisfy OSP

generating refined predicates. [10] proposed a framework that iteratively narrows the bounds on each selection predicate in a query and asks the user to manually refine the predicate within the constrained dimensions. This approach however cannot be extended to support the refinement of join predicates as ACQUIRE does. For select-only queries, [11] seeks only to attain the desired cardinality and disregards proximity. Consequently, it cannot guarantee that the refined query has the least refinement. The BinSearch algorithm [11] is heavily influenced by the order in which predicates are refined; some orders produce accurate results whereas others produce large errors. Unlike ACQUIRE, these techniques don't generate a set of alternative refined queries for the user to choose from. To summarize, ACQUIRE is the first technique to refine select and join queries to meet the dual constraints of proximity to the original query and the desired aggregate constraint.

10. CONCLUSION

We introduce *Aggregation Constrained Queries* that constrain not only the tuples produced by the query, but also aggregates on these tuples. We argue that algorithms targeting ACQs must combine efficient query execution and query refinement. We propose ACQUIRE to tackle ACQs. ACQUIRE adopts the *Expand and Explore* strategy where it iteratively *expands* the original query to minimize refinement and efficiently *explores* refined queries via a novel incremental aggregate computation technique. The general principle of ACQUIRE allows us to support user defined predicate refinement scoring and aggregate error functions. ACQUIRE guarantees that each query is executed at most once, regardless of the number of queries it is contained within thereby exploiting work sharing. This enables ACQUIRE to consistently perform up to 2 orders of magnitude faster and produce queries with 2X smaller refinement than extensions to existing techniques.

ABSTRACT

Ranked lists are an essential methodology to succinctly summarize outstanding items, computed over database tables or crowdsourced in dedicated websites. In this work, we address the problem of reverse engineering top-k queries over a database, that is, given a relation R and a sample top-k result list, our approach, named PALEO¹, aims at determining an SQL query that returns the provided input result when executed over R . The core problem consists of finding predicates of the where clause that return the given items, determining the correct ranking criteria, and to evaluate the most promising candidate queries first. To capture cases where only a sample of R is available or when R is different to the relation that indeed generated the input, we put forward a probabilistic model that allows assessing the chance of a query to output tuples that are resembling or are somewhat close to the input data. We further propose an iterative candidate query execution to further eliminate unpromising queries before being executed. We report on the results of a comprehensive performance evaluation using data and queries of the TPC-H and SSB [14] benchmarks.

1. INTRODUCTION

Reverse engineering database queries describes the task of obtaining an SQL query that is able to generate a specified input table, when executed over a given database instance. This generic problem has various important application scenarios, specifically for top-k database queries that often yield valuable analytical insights. Consider, for instance, business analysts who are interested in determining alternative queries that yield the same or similar query result tuples, data scientists who try to find explanatory SQL queries for crowd-sourced top-k rankings, or to find the data-generating query of a sample input in order to re-execute it on current or future database instances in cases

*This work has been supported by the German Research Foundation (DFG) under grant MI 1794/1-1.

¹PALEO is approximately the reverse of the word OLAP and also emphasizes the goal of assembling queries based on their data footprints (results), much like paleontologists reconstruct and study fossils.

Table 1: Sample relation of telecommunications traffic data

where the original query has not been saved or has not been made public, for one or another reason. The discovered queries can reveal interesting properties of the input, most importantly the constraints to tuples expressed in the “where clause” of the query and how tuples are ranked. The last years have brought up various research results [17, 12, 19] on reverse engineering database queries. Compared to existing approaches that operate on input in form of full tables, reverse engineering top-k queries adds two complex ingredients to the re-engineering task. First, it is the rather small input, consisting of only a few (as k is usually quite short) ranked tuples and, second, the various ways top-k SQL queries can be formulated, given various sorting orders and aggregation functions.

Consider a relation *Traffic*, illustrated in Table 1, containing cellphone-traffic data. The relation contains textual attributes like name of the customer, the city and state the customer lives in, and the tariff plan and the month for which the traffic was realized. In addition, there are numerical attributes that measure the customer’s traffic, like number of minutes talked, the number of text messages (SMS) sent, and the number of spent megabytes of data.

Table 2: Example input list

Table 2 shows a top-k list with two columns and five rows. The input list does not have attribute names (or if it does, are not correlated to the attribute names in the database table). The first attribute is the customer’s name, while the second is the performance attribute according to which the customer ranking was produced. Note that there are no empty cells in the list, all values are specified. Considering the *Traffic* relation of Table 1, we can see that the input ranking list can perhaps be generated using the following query:

```

SELECT name, max(minutes) FROM traffic
WHERE state = 'CA'
GROUP BY name ORDER BY max(minutes) DESC
LIMIT 5

```

This query computes the top 5 customers of the telecommunications company, living in the state of California, ranked by the number of minutes talked in a single month. In general, there can be several different queries that produce the same results; consider for instance augmenting the above query Q with an additional constraint to customers with the tariff plan “XL”, it would leave the result unchanged (including the order among tuples).

1.1 Problem Statement

Given a database D with a single relation R with schema $\mathcal{R} = \{A_1, A_2, \dots\}$ and an input relation L that represents a ranked list of items with their values. **The task we consider in this paper is to efficiently and effectively determine queries Q_i that output tuples that resemble L when executed over R .**

We focus on top-k select-project queries over relation R of the form shown in Figure 1(left). We specifically focus on a single relation to emphasize on the intrinsic characteristics of top-k queries, instead of considering the reverse engineering of joins, too, which has been addressed by Zhang et al. [19] in their recent work on reverse engineering complex join queries.

```

SELECT id, agg(value)
FROM table
WHERE  $P_1$  and  $P_2$  and ...
GROUP BY id
ORDER BY agg(value) LIMIT k

```

L	
$L.e$	$L.v$
e	100
f	90
g	80
m	70
o	60

Figure 1: Query template (left) and example input L (right)

The problem has two properties that can be relaxed or tightened. First, it can either demand determining only one, multiple, or all input-generating queries. Second, the notion of a query being valid in the sense that it resembles the input can be relaxed to a notion of approximately resembling the input.

The problem is challenging for the following reasons: (i) The size of the input list is rather small, it is difficult to derive meaningful (statistical) properties in order to identify valid predicates and ranking criteria, (ii) the relevant subset of R that features all tuples of the entities in L can become very large, and (iii) false positive and false negative candidate queries deteriorate system performance due to many necessary query evaluations and limit the chance to successfully determine a valid query that generates the input.

The presented approach, coined PALEO, is not limited to finding exact matches, but can almost directly be applied to finding queries that compute a ranking L' over R , with L' being similar to L . We get back to this generalization in Section 3.3. We refer to the specific attribute in R that contains the entities the table reports on as A_e and assume it is known a priori.

As already indicated in the template query, we focus on predicates P of the form $P_1 \wedge P_2 \cdots \wedge P_m$, where P_i is an atomic equality predicate of the form $A_i = v$ (e.g., state = “CA”). Furthermore, we denote with $size$ of a predicate $|P|$ the number of atomic predicates P_i in the conjunctive clause.

The input top-k list L has two columns; $L.e$ and $L.v$ denote the entity column and the numeric score column, respectively. Note that L does not contain the name of the

column $L.v$ or the column name of $L.v$ is named for human consumption (e.g., “Total traffic”, which can be total number of minutes, SMS, or data), i.e., not corresponding to the ones present in the database. Hence, referencing to the appropriate attribute in R cannot be done by name. Table 3 shows a summary of the most important notations used throughout this paper.

1.2 Sketch of the Approach

A naïve approach would enumerate all possible queries, say with a limited complexity of the predicate in the where clause, evaluate the queries one-by-one against the database and check whether the returned results resemble the input list. This is clearly beyond hope, even for relatively small databases and schemas.

Our approach, conceptually, loads all tuples from R that contain any of the entities in L . This table is called R' and is used in two subsequent steps, first, to determine the query predicate and, second, to find the right attribute(s) and aggregation function. In case R' is completely given, our approach is extremely effective in determining the individual building blocks of the desired query. When working on a subset of R' , we show how to handle large amounts of potential candidate queries by introducing a suitability-driven order among them, in order to find the desired query early.

1.3 Contributions and Outline

With this paper we make the following contributions:

- To the best of our knowledge, this work is the first to consider the problem of reverse engineering top-k OLAP queries. We present an efficient and effective solution to it, in a flexible and extensible framework.
- We show how to efficiently compute promising predicates using an apriori-style algorithm over R' and how to augment them with ranking criteria using data samples and statistics obtained from the base relation R .
- We present a probabilistic reasoning that allows ordering candidate queries by the likelihood that they compute the input ranking L . This, together with a method to skip unpromising queries dynamically at validation time, allows finding the desired valid queries very efficiently.
- We report on the results of a carefully conducted experimental evaluation using data and queries from the TPC-H [16] and SSB [14] benchmarks.

This paper is organized as follows. Section 2 discusses related work. Section 3 presents the framework and key ideas behind our approach, followed by the specific sub-problems of identifying query predicates in Section 4, and determining the ranking attributes and aggregation function, in Section 5. Section 6 considers handling changed data in R , and proposes a probabilistic model to rank queries by their expected suitability to generate the input. Section 7 introduces an incremental strategy to eliminate unpromising candidate queries based on observed results of already executed candidates. Section 8 reports on the results of the experimental evaluation and presents lessons learned. Section 9 concludes the paper.

2. RELATED WORK

The problem of reverse engineering queries was considered by Tran et al. [17] in their data-driven approach called *Query by Output* (QBO). Given a database D and a query output $Q(D)$ produced by a query Q , they try to find an instance-equivalent query Q' . They focus on identifying the selection predicates in select-project-join queries and formulate this

R	Base table in the database
A_i	Attribute in R
A_e	Entity attribute in R
L	Top-k input list
$L.e$	Entity column in L
$L.v$	Ranking column in L
e_i	Entities in A_e or $L.e$
v	Values in A_i
P	Predicate (atomic or conjunctive)
Q	Query
$Q(R)$	Result set of Q when querying R

Table 3: Overview of Notations

problem as a data classification task. For generating the selection conditions they use a decision tree classifier that is constructed in a top-down manner in a greedy fashion by determining a “good” predicate according to which the tuples are split into two classes. These two classes would then form the root nodes of two decision trees (constructed recursively).

Sarma et al. [12] explore the *View Definitions Problem* (VDP) which is a subproblem of QBO in that it considers only one relation R and there are no joins and projections. Thus, they only try to find the selection condition of the view V and do this looking at the problem as an instance of the set cover problem. From the families of queries that they cover, we focus on conjunctive queries with a single equality predicate and conjunctive queries with any number of equality predicates. For both types they propose naïve algorithms that utilize the size of the attribute domains in the view. Zhang et al. [19] compute a generating *join query* that produces a table $Q(D)$ from the tables in D . The generated join query does not have selection conditions and they focus mostly on identifying the joins using graph structures following foreign/primary-key links.

Shen et al. [13] study the problem of discovering a minimal project-join query that contains given example tuples in its output and do not consider selections. They only handle text columns with keyword search allowed on them and introduce a candidate generation-verification framework to discover all valid queries. By using common sub-join trees of the candidate queries as filters they manage to improve the efficiency of their approach.

Psallidas et al. [10] propose a candidate-enumeration and evaluation framework for discovering project-join queries. Their system handles only text columns and establish a query relevance score based evaluation of candidate queries. The system returns the PJ queries with the top-k highest scores and it discovers not only the queries that exactly match the given example tuples. Moreover, they propose a caching-evaluation scheduler, where they dynamically cache common sub-expressions that are shared among the PJ queries. Join queries are orthogonal to our work and none of the above approaches handle top-k aggregation queries.

In keyword search over databases [2], the input is a single tuple with specified keywords as fields. The works of [5, 15] interpret the query intent behind the keywords and compute aggregate SQL queries. Blunschi et al. [5] use patterns that interpret and exploit different kinds of metadata, while Tata et al. [15] discovers aggregate SQL expressions that describe the intended semantics of the keyword.

The principle of reverse query processing is studied in [3, 4, 6, 9], however their objectives and techniques are different. Binning et al. [3, 4] discuss the problem of generating a test database D such that given a query Q and a desired result R , $Q(D) = R$. Bruno et al. [6] and Mishra et al. [9] study the problem of generating test queries to meet certain cardinality constraints on their subexpressions.

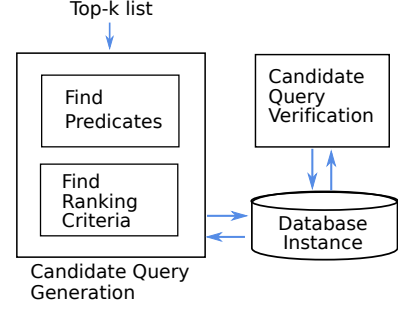

Figure 2: System task steps

A reverse top-k query [18] returns for a point q and a positive integer k , the set of linear preference functions (in terms of weighting vectors) for which q is contained in their top-k result. For example, finding all customers who treat the given query product q as one of their top-k favorite elements. In such cases, each customer is described as a vector of weights. Although it appears related given the name, this research area is not directly related to our work.

3. APPROACH

The task of reverse engineering top-k queries is split into the following three steps, illustrated in Figure 2:

- **Step 1:** find the predicate P in the where clause of Q
- **Step 2:** find the ranking criteria
- **Step 3:** validate queries

As the basis of further computation, we first retrieve from relation R all tuples whose entity column contains one of the entities of the input table L ; we call the resulting table R' .

3.1 Table R'

Consider a top-k list L as shown in Figure 1. Let $e_i \in \{e, f, g, m, o\}$ denote the entities in the column $L.e$.

By using a standard database index, such as a B+ tree, on the entity attribute of R , we can efficiently retrieve R' (shown in Table 4) containing all tuples from R matching any of the entities $e_i \in L.e$. Whether the index is actually used or the query optimizer decides to perform a table scan is not a concern here. In any case, in this example, the query to compute R' is

```
SELECT * FROM R
WHERE  $A_e$  IN [e, f, g, m, o]
```

For the purpose of efficient access of its data, PALEO stores R' in-memory in a **column oriented** fashion, with columns being represented as arrays, allowing fast evaluation of aggregate queries over R' . The relation R' has $k' \geq k$ number of tuples, since it contains all tuples without (potentially) being filtered by predicates. In fact, it is reasonable to assume, without prior knowledge, that $k' \gg k$, as each distinct entity e_i can appear many times in R . We will allow to work on a subset (samples) of R' in Section 6, and study the consequences, but for now we assume R' in fact covers *all* tuples of *any* entity of the input.

3.2 The Three Steps

Candidate Predicates Identification. Using the tuples in R' we create a set of *candidate predicates* that are subsequently augmented with ranking criteria to make up full-fledged candidate queries.

DEFINITION 1. Candidate Predicate

We say a predicate P is a candidate predicate iff for each entity that appears in L there is a tuple t in R' that fulfills the predicate. Formally,

$$\forall e_i \in L.e \exists \text{ tuple } t \in R' : P(t) = \text{true} \wedge t.e = e_i$$

It is easy to see that a candidate predicate can potentially produce the top-k input list. In other words, having a candidate predicate in the where clause is a *necessary criterion* of a query to be a valid query, but it is *not a sufficient criterion*. This is because a candidate predicate can still “let through” tuples of other entities (that are not in the input table L) that can be ranked higher than the tuples in L , hence, the query is not a valid query as the output does not match the input.

COROLLARY 1. Downward-closure (anti-monotone) property of the candidate predicate criterion. *Given a predicate P_1 that is not a candidate predicate, then a predicate P_i such that $P_1 \subseteq P_i$ (that is, all sub-predicates in P_1 are also present in P_i) can not be a candidate predicate.*

The corollary follows immediately from the definition of candidate predicates: any predicate P_i with $P_1 \subseteq P_i$ for another predicate P_1 evaluates to true for a subset of tuples for which P_1 evaluates to true. This property is used to prune the searchspace in Section 4, similar to what the apriori algorithm [1] does for the support measure.

Ranking Criteria Identification. In the *second step* of our approach, we identify the ranking criteria according to which the entities in the top-k list are ranked. For this purpose we need to find a suitable numeric attribute (or multiple ones) including an aggregation function—or decide if one is used at all.

DEFINITION 2. Candidate Ranking Criterion

We say a ranking criterion, consisting of one or multiple numerical attributes and, if existing, an aggregation function is a candidate iff, **when executed on R' together with a candidate predicate, it returns a result identical to the input list L .**

This definition is very reasonable but similar to the criterion to identify candidate predicates it is only a necessary condition to a valid ranking criteria for a query when executed over the entire relation R . It is, however, not a sufficient condition, as when executed on R there can be still other entities, not in L , that are disturbing the “correct” order. The case of partial matches is discussed below.

Candidate Queries Identification and Evaluation. Using the candidate predicates and the valid ranking criteria we can form candidate queries. Each candidate query is executed on R and the results are compared with the input top-k list. The queries that produce instance-equivalent results with the original query are the valid queries.

3.3 Allowing Partial Matches

Like other approaches on reverse engineering queries, this approach can be relaxed to allow finding also partially matching queries. This can be useful for cases where the input L has been obtained from an older instance of the database or in cases where L has been generated in the extreme, through crowdsourcing top-k rankings. Our approach can be adapted to such partial match scenarios as follows. First, the condition to accept a query during the validation phase needs to be switched to accepting partial match. For comparing rankings, there exist several ways, most prominently Spearman’s Footrule distance and Kendall’s Tau. Fagin et al. [7]

	R'									
$t.id$	E	A	B	C	\cdots	N_1	N_2	N_3	\cdots	
1	e	a_1	b_9	c_3	\cdots	75	4	5	\cdots	
2	e	a_1	b_8	c_1	\cdots	100	8	7	\cdots	
3	e	a_3	b_1	c_6	\cdots	45	15	1	\cdots	
4	f	a_1	b_8	c_1	\cdots	90	16	2	\cdots	
5	f	a_5	b_4	c_6	\cdots	35	23	3	\cdots	
	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	
10	g	a_1	b_8	c_3	\cdots	80	42	14	\cdots	
	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	
20	m	a_1	b_8	c_4	\cdots	70	29	10	\cdots	
	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	
30	o	a_1	b_8	c_4	\cdots	60	31	7	\cdots	
	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	\cdots	

Table 4: Example of a Relation R' for Input L in Figure 1

show how these measures can be applied to top-k lists. In our case of ranking with two columns (entity and value) we would compute such methods on the entity column; and can additionally compute a distance measure like L1 or L2 on the values if numerical or otherwise use a distance like the set-based Jaccard distance. Second, not taking for granted that we cannot precisely reverse engineer the input L implies that even a fully known R' would behave exactly like being a sample, with the consequences described in Section 6. That means, we can directly apply the reasoning on query suitability explained there.

4. CANDIDATE PREDICATES

The task we consider in this section is to find all k -sized candidate predicates P_i . Each predicate can be simple atomic equality predicate like $(A = a_1)$ or conjunctions of atomic equality predicates, e.g., $(A = a_1) \wedge (B = b_8)$. Candidate predicates are determined over the table R' , as described above. From Definition 1 we know that in order to be a candidate predicate, a predicate P has to have for *each* entity in the input $L.e$ at least one tuple in R' with $P(t) = \text{true}$.

This criteria is anti-monotone (aka. downward-closed), i.e., a predicate P_i with size k can be considered a candidate predicate if and only if all its sub-predicates are also candidate predicates. This problem is similar to frequent itemset mining for which the apriori principle and algorithm [1] is widely known. In data mining terminology, itemsets resemble the values that are used to form the candidate predicates.

The method to compute candidate predicates in PALEO is described in Algorithm 1. In the first step, $k = 1$, we start by identifying all atomic candidate predicates, i.e., the predicates with size $|P_i| = 1$ (Lines 2–6 in Algorithm 1). For this purpose for each column A_i we identify values v such that the predicate $P_i := (A_i = v)$ is a candidate predicate (Lines 3–4 in Algorithm 1). Furthermore, for each such created P_i we keep a set \mathcal{I}_{P_i} containing the tuple ids (aka. row ids) that this predicate selects, i.e., $\mathcal{I}_{P_i} = \{t.id | P_i(t) = \text{true}\}$. In each additional step, conjunctive predicates of size k are created, by adding atomic predicates from the set \mathcal{P}_1 to the predicates created in the previous iteration (Lines 7–14 in Algorithm 1). The algorithm does not create a predicate multiple times. The conjunctive predicate P_{ij} whose tuple ids set $\mathcal{I}_{P_{ij}}$ covers all entities in the input list is added to the set of candidate predicates with size k (Lines 12–13) and will be used in creating candidate predicates of size $k + 1$ in the next iteration.

Example: Considering Table 4 and the input list in Figure 1, we create atomic predicates starting with column A as we iterate over its values a_i . Note that the entities in E are sorted. The set of atomic candidate predicates is created, $\mathcal{P}_1 = \{P_1 := (A = a_1), P_4 := (B = b_8)\}$. These two predicates are candidates, since the tuples that fulfill the predicates cover all entities in the input list L . Furthermore, the set tuple ids that the predicates select are kept, e.g., $\mathcal{I}_{P_1} = \{1, 2, 4, 10, 20, 30\}$. If added as a selection condition,

method: **findPredicates**

input: top-k list L
relation R'

output: a set of candidate predicates \mathcal{P}

```

1  $\mathcal{P} = \emptyset$ ;  $k = 1$ ;  $\mathcal{P}_k = \emptyset$ 
2 for each  $A_i$  in  $R'$ 
3   find  $P_i := (A_i = v)$  with  $|P_i| = 1$  s.t.
4    $\forall e_i \in L.e \exists \text{ tuple } t \in R' : P_i(t) = \text{true} \wedge t.e = e_i$ 
5   add  $P_i$  to  $\mathcal{P}_k$ 
6   for each  $P_i$  keep  $\mathcal{I}_{P_i} = \{t.id | P_i(t) = \text{true}\}$ 
7 repeat
8    $k = k + 1$ 
9    $\mathcal{P}_k = \emptyset$ 
10  for each  $P_i \in \mathcal{P}_1$  and  $P_j \in \mathcal{P}_{k-1}$  and  $P_i \cap P_j = \emptyset$ 
11    create  $\mathcal{I}_{P_{ij}} = \mathcal{I}_{P_i} \cap \mathcal{I}_{P_j}$ 
12    if  $\mathcal{I}_{P_{ij}}$  covers all  $e_i \in L.e$ 
13      add  $P_{ij} := P_i \wedge P_j$  to  $\mathcal{P}_k$ 
14 until  $\mathcal{P}_k = \emptyset$ 
15 return  $\mathcal{P} = \bigcup_k \mathcal{P}_k$ 

```

Algorithm 1: Finding candidate predicates

these candidate atomic predicates would result in a candidate query.

In each next step, we try to produce conjunctive clauses of size k from the predicates in \mathcal{P}_1 and \mathcal{P}_{k-1} . Thus, for $k = 2$, we test if the predicate $P_{14} := (A = a_1) \wedge (B = b_8)$ qualifies as a candidate by intersecting the corresponding sets of tuple ids. Since the intersected tuple ids in $\mathcal{I}_{P_1} \cap \mathcal{I}_{P_4} = \{2, 4, 10, 20, 30\}$ cover all entities in $L.e$, the predicate P_{14} is a candidate predicate. Recall that R' is held in memory and that we can, via tuple ids, very efficiently access the full tuple to check whether or not it matches the predicate.

Properties of the Algorithm:

- (i) The algorithm is **correct** with respect to R' , that is, predicates returned by the algorithm are guaranteed to be candidate predicates, following Definition 1. Further, the algorithm is **complete**, that is, it finds all possible candidate predicates over R' .
- (ii) When predicates are applied in R instead of R' they can also let tuples with entities that are not in L pass, which leads to **false positive** candidate queries.

The difference to the apriori algorithm that operates on the support measure is that apriori counts the frequency of *all* itemsets and then determines the ones above the specified threshold. In our algorithm, we eliminate a predicate as soon as we find that it does not cover a certain entity. The same happens in each additional pass, since apriori will generate all the pairs of frequent items and count their appearance. Thus, all pairs that contain a false positive singleton will also be false positives.

Figure 3: Mapping from tuple set to predicates.

4.1 Tuple Sets and Predicates

Some of the created candidate predicates have identical tuple sets \mathcal{I}_{P_i} . These predicates select the same tuples in R' and share the same data characteristics regarding to R' . Thus, candidate predicates are grouped according their tuple

Figure 4: Order of looking for the ranking criteria

sets, i.e., if $\mathcal{I}_{P_i} = \mathcal{I}_{P_j}$, then P_i and P_j would belong to the same group.

Figure 3 depicts a tuple set mapped to a group of candidate predicates created from the tuples in Table 4. The predicates P_4 and P_{14} cover the same tuples in Table 4. Thus, for these predicates, it is enough to examine the data characteristics of the tuples in the tuple set \mathcal{I} .

5. RANKING CRITERIA

In order to find the ranking criteria according to which the ranking in the top-k list is done, PALEO operates on the distinct tuple sets, determined in the algorithm above. If relation R , and hence also R' , is identical to the database state when the input data was once generated, it is guaranteed that PALEO is able to determine the valid ranking criteria.

The actual size of R' depends naturally on the size k of the input list L and also on the data characteristics, i.e., how many tuples R contains for a single entity. We expect R' to be holding a factor of k/n less tuples than R , where n is the number of distinct entities in R , and that this allows to load R' entirely in main memory. While it might be reasonably cheap to execute a query on this R' in memory, note that we have to possibly do so very many times to identify suitable ranking criteria. That is, depending on the size of R' we can potentially reduce the runtime of our algorithm if it can be avoided to work on R' directly.

The idea is to harness small data samples, histograms, or simple descriptive statistics computed upfront from the base relation R in order to select a subset of potentially useful columns without touching R' . However, there might be invalid criteria identified or potentially also no criteria at all, given the limited coverage of data samples and the impreciseness of histograms. Therefore, identified candidate ranking criteria are validated on R' and in case no heuristic is applicable or was not successful, the whole ranking criteria identification is executed on R' .

Depending on the aggregation function we aim at checking for suitability, we can or cannot use some of these techniques. For instance, comparing the entities in L with the top entities stored for each column of R can be applied to queries with *max* aggregate function, but not directly to queries using *sum* as the aggregation function. Figure 4 summarizes this observation. Traversing the tree pre-order depth-first is the way PALEO looks for the ranking criteria, with the leaf nodes showing the order in which the techniques are applied. The system tries to identify the ranking criteria with smaller search space first. Thus, for instance, if the valid ranking criteria is *max(A)* and comparing the top entities produces valid results, only the shaded part of Figure 4 will be processed.

5.1 Top Entities

The most apparent first attempt to identify an attribute according to which tuples are sorted in L is to store for each attribute in R the topmost entries, when sorted by the specific attribute. Then, we intersect the input entity set

method: **topEntities**

input: top-k list L
relation R'

output: a set of candidate numerical columns \mathcal{A}_C

```

1  for each  $A_i$  in  $R'$ 
2      if  $A_i$  not numerical, then skip  $A_i$ 
3      if  $\max(v \in A_i) < \max(v \in L.v)$ , then skip  $A_i$ 
4      if  $\min(v \in A_i) > \min(v \in L.v)$ , then skip  $A_i$ 
5      if  $|A_i| < |L.v|$ , then skip  $A_i$ 
6      if  $TopE(A_i) \cap L.v \neq \emptyset$ , add  $A_i$  to  $\mathcal{A}_C$ 
7  return set of candidates  $\mathcal{A}_C$ 

```

Algorithm 2: Finding candidate columns with top entities

from L with these top entries. More than just the k top values are stored to increase the chance that these entities do overlap with the entities in L . Clearly, it should also not be too large such that each numeric column appears promising. The exact way of how this idea is applied is shown in Algorithm 2, line 6.

Before this is done, PALEO filters out attributes by applying three simple checks: it compares the max (min) values of the input list and the column and if the column's value is smaller (greater) than the max value of the input list it does not intersect the entities (Algorithm 2, line 3 and 4). Additionally, the number of distinct values is compared: If the column has less distinct values than the input list, we skip this column (Algorithm 2, line 5).

The numerical columns that result in a *non-empty intersection* are considered as candidate numerical columns. Thus, using R' and the tuple sets created in finding candidate predicates, they are checked whether they can match the ranking in the top-k input list.

5.2 Querying Histograms

In the case no candidate numerical columns have been identified with the above intersection of top entities, PALEO employs histograms describing an attribute's frequency distribution in order to find candidate attributes that appear suitable for ranking. As we consider only numeric attributes to be used as the bases of ranking criteria, such a histogram describes how frequent a specific numeric value appears in the attribute's column in relation R . One idea is comparing the value-frequency distributions of the histogram of the input list with the histograms of the numerical columns in R , by using histograms distance measures such as Earth Mover's Distance [11]. However, a top-k list is inherently small and does not contain enough elements to provide a meaningful distribution. Hence, PALEO samples each attribute's histogram and calculate the L1 distance between its top-k values and the input values. Similar to using top entities of each column, we draw samples following the distribution described in the histogram. PALEO uses equi-width histograms having 1000 cells each.

This is done for each attribute, which allows ordering all attributes by the L1 distance of the sampled data to the data in L . Depending on the data in the table, if there is a column with similar values and distribution as the column we are looking for, it is possible that the correct column does not have lowest L1 distance. In order to account for this, we consider the top 30% of the columns in the list as candidate attributes.

5.3 Validation over R'

As a validation for the possible ranking criteria identified above, we use the tuples in R' . In the case when we have successfully identified candidate attributes with the previous techniques, we first check if any of these candidate attributes

can produce the ranking. For this purpose, we go through the distinct tuple sets \mathcal{I}_i we computed in Section 4 and check which of the candidate numerical columns, i.e., their sorted aggregated values exactly match the input L .

Some of the supported ranking criteria cannot be identified by the above mentioned techniques, requiring more complicated statistics and this is beyond the scope of this paper. For instance, with the *avg* and *sum* aggregate functions, the top entities for a column depend heavily on the predicate, since the values are aggregated over multiple tuples. Similarly, harnessing histograms with *sum* would involve convolutions of the histograms of the pairs of columns.

As a fall back, if none of the candidate attributes can produce the ranking criteria, we revert to checking the remaining numerical columns in R' that were not found as candidates. We still use only the tuples with tuple ids found in the tuple sets \mathcal{I}_i . For each tuple set and each numerical attribute in R' that passes our (three) simple checks (i.e., min, max comparison, and number of distinct items), we compute whether the tuples in \mathcal{I}_i if sorted according to the specific attribute and aggregate function are identical to L . After identifying the appropriate numerical attribute and aggregate function, we can filter out some of the *candidate predicates*. If a certain tuple set does not contain the input numerical values, we **remove** this tuple set and all the candidate predicates that correspond to it from the candidate predicates.

6. HANDLING VARIATIONS OF R

The techniques behind PALEO discussed so far are based on the assumption that exactly the same relation R that produced the input list L is available and that it is feasible to operate on it directly. However, it might appear that tuples in R have changed, for instance, because of inserts, updates, and deletes, due to slowly changing dimensions [8] in data warehousing scenarios, or only a subset (sample) is available. In this section, we describe how PALEO deals with situations when only subset of the original tuples in R is available.

This assumption has direct consequences on PALEO's ability to accurately identify suitable predicates and ranking criteria. As we have discussed above, determining query predicates with the proper table R at hand *only* leads to obtaining **false positives** in the candidate predicates, introduced by additional entities outside R' that qualify for the predicate. The changed data further introduces **false negatives**. That is, the query that generated the input might not be found at all, although such a query exists. This is caused by missing or modified tuples in R that would be required to unveil a predicate to be fulfilled by all of the k entities. False negatives are synonym to *loss in recall*, i.e., the fraction of found queries to all existent queries that generate the input.

We address this by

- Reasoning about likelihood of being a successful query.
- Smart evaluation to skip unpromising queries.

Variations in R means also variations in R' . Let us denote the table stemming from the modified base table as R'' . It can happen that R'' does not contain tuples from all entities from the input list, for instance if all tuples for a certain entity $e_i \in L.e$ have been deleted from R . Recall that the method for finding predicates, described in Algorithm 1 demands that a predicate must cover all entities of the input list $L.e$.

Now, it is possible that the tuples containing the valid predicate for a certain entity have changed in the columns that comprise the predicate. Then, it is impossible to precisely validate or invalidate the predicate using the method in Algorithm 1: Being strict, missing the tuples with the

valid predicate for a certain entity will lead to evicting the valid predicate even though the majority of entities in R'' contain tuples with it, thus resulting in false negatives. To avoid that, the condition of evicting a predicate is relaxed. Instead of demanding that a predicate is considered as a candidate predicate if it covers all distinct entities in R'' , we ask for it to cover the *majority of the entities*, thus taking into account that some entities can have tuples with the valid predicate missing. Another possible approach is not to evict predicates at all, i.e., form all the predicates that we encounter in R'' while not demanding any entity covering. This might, however, result in very many candidate predicates with too many false positives. Executing candidate queries for all such predicates will drastically decrease the overall efficiency of PALEO.

We describe a probabilistic model of assessing candidate predicates when the data in the base table has changed and how uncertainty in finding ranking criteria can be handled.

6.1 Assessing Candidate Predicates

Changes in R introduce uncertainty in finding the valid predicates. To account for such changes, the condition of evicting a predicate is relaxed. As a result, our methods identify more candidate predicates that need to be assessed whether or not they are likely to be indeed a valid predicate. This assessment is later used when executing queries in the final step such that queries can be executed in increasing order of the likelihood to be in fact a valid query.

A candidate predicate P_i identified from the table R'' is a false positive if: $\exists e_i \nexists t \text{ s.t. } P(t) = \text{true}$. In other words, if for a certain entity e_i there is no tuple for which the predicate P is valid, then this predicate is a false positive. This means that a query with this predicate would return a top-k list without the entity e_i .

Consider a predicate P over the attributes A_1, \dots, A_m . The probability that a tuple exists in relation R is given by the number of distinct entries of the columns A_i (i.e., $|A_i|$) as

$$P[\text{tuple exists}] = \prod_i \frac{1}{|A_i|}$$

Consider an entity e_j for which we did not find a tuple that matches the predicate and let $unseen(e_j)$ be the number of changed tuples of entity e_j , then

$$P[\text{won't see for } e_j] = (1 - P[\text{tuple exists}])^{unseen(e_j)}$$

The probability that at least one entity is rendering this predicate to be a false positive (by not providing a matching tuple) is thus given as

$$P[\text{false positive}] = 1 - \prod_j (1 - P[\text{won't see for } e_j])$$

6.2 Approximating Ranking Criteria

Operating on R'' also introduces uncertainty in finding ranking criteria. Since not all tuples for each entity e_i are the same, the ranking criterion cannot exactly match the numerical values in the input top-k list. This is why there is a need of measuring the suitability of each candidate ranking criteria to the input list. For this purpose, we compute the distance between the input values and the candidate attribute(s) values. We use the L1 distance (aka. Manhattan distance) that is simply the sum of absolute differences in the numeric values.

Queries without sum: The changes in the tuples for an entity e_i renders the **topEntities** method (Section 5.1) not directly applicable. Without the identical tuples, it is difficult to match the candidate numerical columns with the input ranking values. Using the L1 distance and the column

values in R'' (Section 5.3) provides the possibility to compute the suitability of the candidate ranking columns. That way, each candidate column has a corresponding L1 distance that is used in ranking the candidate queries.

Queries with sum: The **sum** aggregate function sums up all values for a certain entity e_i . Since with changed data some of the tuples for an entity are missing, they need to be approximated. We do this by using the column values for the column(s) in R' . Using this approximation, the L1 distance to the input ranking values is calculated and then used for ranking the suitability of the column(s).

The approximation of the sum for each entity is done using the tuple id sets. We take a look at the more complicated case of having a sum of two columns A_i and A_j . Thus, for a predicate P with a corresponding tuple set \mathcal{I}_P , for each entity e_i let $sum_{A_{ij}}(\mathcal{I}_P)$ denote the sum of the values, of the columns A_i and A_j , of the tuples in R'' with tuple ids in \mathcal{I}_P that have an entity e_i , i.e.:

$$sum_{A_{ij}}(\mathcal{I}_P) = A_i(\mathcal{I}_P) \text{ op } A_j(\mathcal{I}_P) \text{ s.t. } t.e = e_i, \text{ op} \in \{+, *\}$$

Additionally, let $\#v$ denote the number of tuple ids in the tuple set \mathcal{I}_P of the entity e_i , i.e., the number of tuples that the predicate P selects with e_i . We approximate the sum as:

$$appxSum_{e_i}(\mathcal{I}_P) = \frac{sum_{A_{ij}}(\mathcal{I}_P)}{\#v} \times (\#v \times \frac{|e_i|_{R''}}{|e_i|_{R''} - unseen(e_i)})$$

where $|e_i|_{R''}$ is the number of tuples in R'' for the entity e_i . Thus, for each entity e_i , the average summed value from the sampled tuples is multiplied with the approximated selectivity of the predicate P . The sorted list $appxSum(\mathcal{I})$ formed from the sums for each entity $appxSum_{e_i}(\mathcal{I}_P)$ is then used for calculating the L1 distance d to the input list and ranking the candidate column pairs.

6.3 Combined Model

The queries formed from the combination of candidate predicates and ranking criteria need to be validated by executing them on R . The order of execution is done ordered by a suitability value for each candidate query Q_c . The suitability is computed as:

$$s(Q_c) = (1 - P[\text{false positive}]) \times (1 - d)$$

where $P[\text{false positive}]$ is the probability of the predicate in the candidate query of being a false positive and d is the max normalized L1 distance between the ranking criteria in Q_c and the numerical values in the input list L .

6.4 Working with Samples of R'

Consider a scenario where it is impossible or unfeasible to work on the complete relation R' (the subset of R of all tuples that contain any of the entities in L). This relation R' can be very large, potentially as big as R , if there are many tuples for each distinct entity—a typical case in data-warehousing applications that often aggregate large amounts of observations of a specific entity. The probabilistic model for assessing candidate predicates together with the approximation of the ranking criteria can also be applied to such a scenario as well.

We consider two approaches of sampling. First, we sample by retrieving all tuples for a certain (e.g., randomly selected) subset of the entities in L . In this way, we do not get any false negatives and the candidate predicates set is a superset of the valid predicates. This is because having all tuples in R'' for a certain entity is guaranteed to contain the tuples with valid predicates. As a result, our algorithm will create the predicate as a candidate. However, the drawback of this approach is having too many false positives. This can

especially happen if for a sampled entity there are too many tuples in the base table R . This will lead to creating a large amount of false positives which impairs efficiency.

Sampling uniformly from all entities mediates this problem, thus sampling a certain percentage of the tuples from each entity. This way, possibility of false positives is decreased, at the price of an increased possibility of false negatives. We encounter the same problem as if we would sample by tuple: it can happen that tuples that contain a valid predicate are not sampled for a certain entity. Relaxing the condition of evicting a predicate mediates this problem.

We can draw a parallel between the scenarios of having modified data in R and sampling. The tuples that are sampled in R'' correspond to the tuples in the base table that have the columns comprising the valid predicate **unmodified**. Hence, the not sampled tuples are analogous to the ones that are modified.

Consider a predicate P_i that is a valid predicate for an entity e_i . The probability that k tuples with the valid predicate are sampled in R'' has a hypergeometric distribution, i.e.,

$$P[k \text{ tuples sampled}] = \frac{\binom{K}{k} \binom{N-K}{n-k}}{\binom{N}{n}}$$

where K is the total number of tuples with the predicate in R' , N is the total number of tuples to sample from, i.e., $N = |R'|$, and $n = |R''|$ is the number of sampled tuples.

The probability of sampling at least one tuple with the valid predicate P_i for an entity e_i :

$$P[\text{one tuple sampled}] = 1 - \frac{\binom{K}{0} \binom{N-K}{n-0}}{\binom{N}{n}}$$

Considering an input top- k list with m distinct entities e_i and assuming independence in the sampling from the different entities, the probability of seeing a tuple with the valid predicate is:

$$P[\text{all } e_i] = P[\text{one tuple sampled}]^m$$

Intuitively, this probability describes that increasing the sampling size increases the probability of sampling a tuple with the valid predicate for each distinct entity. Consequently, making the condition of evicting a predicate more strict as the sample size increases is needed, i.e., increasing the number of entities e_i that are covered by a predicate so it can qualify as a candidate predicate. This would eliminate the creation of too many false positives with larger sample sizes.

7. SMART QUERY VALIDATION

Ordering candidate queries by their expected suitability to answer the input L promises to find a valid query early—ideally at the first query execution. Even if more than one valid query is to be found, such an order is accelerating the discovery process immensely. We will show in the experimental evaluation that this is indeed the fact.

Now, instead of purely trusting the order, it would be careless to simply execute queries sequentially in the given order, without trying to benefit from information learned while executing them. Consider a candidate query Q_c that is executed and yields a result $Q_c(R)$ that is very similar to the input list L , but is still not an exact match. It would be preferable to continue validating queries that are similar to Q_c and skip those in the ordered query candidate list \mathcal{C} that are not.

It is clear that the similarity (overlap) of the results of a candidate query when executed over R and input list L can be directly computed, using Jaccard similarity for instance. But for the not-yet-executed queries we do not have direct insight on their result, but we can “speculate” about it: We model this similarity between Q_1 and Q_2 by two means; first,

method: resultDrivenValidation

input: ordered list of candidate queries \mathcal{C} ;
Jaccard similarity threshold τ

output: a valid query Q_v

```

1   $Q_c := \mathcal{C}.first$ 
2  /* search for first query with results overlapping L */
3  while  $J(Q_c(R).e, L.e) < \tau$ 
4     $Q_c := \mathcal{C}.next$ 
5  /* keep this first match query */
6   $Q_{fm} := Q_c$ 
7  foundR := false
8  foundR := true if  $J(Q_c.v, L.v) > \tau$ 
9  while( $\mathcal{C}.hasNext$ )
10    $Q_c = \mathcal{C}.next$ 
11   /* skip query  $Q_c$ ? */
12   if  $(P(Q_c) \cap P(Q_{fm}) = \emptyset \text{ or } (foundR \text{ and } R(Q_{fm})! = R(Q_c)))$ 
13     continue
14   execute  $Q_c$ 
15   return if found valid
16 resultDrivenValidation(skipped  $Q_c$ )
```

Algorithm 3: Result driven candidate query validation

by the common atomic equality predicates in the conjunctive where clause, and second, by the use of the same (or not) ranking criteria. For this, with $R(Q)$ we denote the ranking criterion of a query and with $P(Q)$ the set of its atomic predicates.

For each executed query we check if its output matches the input list. In the first part of the algorithm presented in Algorithm 3, we sequentially test the candidate queries until we have found for which the entities in its results are similar to the entities in $L.e$. This query is denoted Q_{fm} , for “first match query”. We also check if the numeric values of the query result are similar to the numeric values $L.v$ of the input list L , again, using the Jaccard similarity. If they are sufficiently similar, we mark the ranking criteria of query Q_{fm} as valid. In the second while loop (line 9–13 in Algorithm 3), we iterate over the remaining candidate queries and skip those queries whose predicates are not at all overlapping with the predicates in Q_{fm} . We further skip queries that have a different ranking criterion to the one of Q_{fm} (line 12 in Algorithm 3), in case this was found as valid.

If by the end of the query list \mathcal{C} a valid query is not found, the algorithm is called for the previously skipped queries, until all queries are evaluated or one valid query is found.

8. EXPERIMENTAL EVALUATION

We have implemented the approach described above in Java. Experiments are conducted on a 2× Intel Xeon 6-core machine, 256GB RAM, running Debian as an operating system, using Oracle JVM 1.7.0.45 as the Java VM (limited to 20GB memory). The base relation R is stored in a PostgreSQL 9.0 database, with a B+ tree index on R ’s entity column.

Datasets. We evaluate our approach of computing instance-equivalent queries using data and queries of two benchmarks, **TPC-H** [16] and the **SSB** [14]. For this, we created a scale factor 1 instance of both TPC-H and SSB data and materialized a single table R by joining all tables from their respective schema. The table R results in 57 and 60 columns, for TPC-H and SSB, respectively. The column c_name (from the customer table) acts as the entity column. We obtain tables with the characteristics described in Table 5.

	TPC-H	SSB
# Tuples	5,313,609	6,001,171
# Entities	171,753	20,000
# Textual columns	27	28
# Non-key numerical columns	13	20
# Avg tuples per entity	31	300
Highest # tuples per entity	187	579

Table 5: Table R characteristics

	Query	sel.
T P C - H	$\gamma_{c_name, MAX(o_totalprice)}$ $(\sigma_{p_type='MEDIUM POLISHED STEEL'$ $\wedge r_name='AMERICA'(R))$	0.001
	$\gamma_{c_name, SUM(ps_supplycost+ps_availqty)}$ $(\sigma_{n_name='JAPAN'$ $\wedge p_container='JUMBO BAG'$ $\wedge l_shipmode='TRUCK'(R))$	0.0001
	$\gamma_{c_name, AVG(lo_revenue)}$ $(\sigma_{s_nation='UNITED STATES'$ $\wedge p_category='MFGR\#14'(R))$	0.002
S S B	$\gamma_{c_name, SUM(lo_extendedprice*lo_discount)}$ $(\sigma_{p_brand='MFGR\#2221'$ $\wedge s_region='ASIA'$ $\wedge d_year=1995(R))$	0.00003

Table 6: Example queries and their selectivity

We examine the applicability of our approach with variation of data in R , by performing experiments with sampling. As described in Section 6, operating on a sample of R has similar characteristics as working on a table R with modified data.

Queries. There are 13 and 22 queries available in the TPC-H and SSB benchmark, respectively. We adjusted the original queries by creating different query types ($max(A)$, $avg(A)$, $sum(A)$, $sum(A+B)$, $sum(A*B)$, and no aggregation), supported by PALEO (cf., Figure 4). We only write the ranking criteria when discussing the different query types. In order to examine the effects of the predicate size and selectivity factor, in each query, we vary the predicate size $|P|$, with $|P| \in \{1, 2, 3\}$. Queries with larger predicates have higher selectivity. Furthermore, all queries have the column c_name as an entity column. Example queries and their selectivity are shown in Table 6.

We execute each query Q over the table R to produce the top- k lists L . Using the LIMIT clause, we create top- k lists with $k \in \{5, 10, 20, 50, 100\}$. Then, we execute PALEO with inputs L and the table R . For the experiments involving sampling, we perform the experiments three times for each input list L and report on the **median** performance. In order to examine the effects of different sample sizes, we created experiments with sample size of 5%, 10%, 20%, and 30%. We keep the 1,000 top entities for each numerical column.

Using the B+ tree on R , for each input list we retrieve (a sample of) R' and store it in memory. Thus, identifying the candidate predicates and ranking criteria are in-memory processes. Without using any compression techniques, the memory consumption of R' in our experiments was around 500MB. The query validation step is done by issuing queries to the underlying PostgreSQL database that resides on disk. Finally, queries show similar results depending on the number of columns in the aggregate function. Thus, for the sake of brevity, we discuss the results of $max(A)$ queries as representative of single column queries and $sum(A+B)$ for the two column queries. Finally, although PALEO discovers all valid queries for an input list, we focus on the efficiency of discovering the first valid query in the presented results.

Figure 5: Number of query executions until first valid query with all tuples for TPC-H dataset

Figure 6: Number of query executions until first valid query with all tuples for SSB dataset

Valid query discovery. PALEO **always** discovers all valid queries for any of the supported query types when having available the entire table R' . The availability of all tuples ensures that false negatives are avoided, and introduces only (a small number of) false positives.

We observe that with all tuples from R' available, our system requires very few query executions in order to identify a valid query. Thus, for $sum(A+B)$ queries and the TPC-H dataset, the average number of query validations amounts to only 1.1 for $|P|=1$, 1.3 for $|P|=2$, and 2.1 for $|P|=3$. In fact, for both TPC-H and SSB, **only a single query validation** is required for 76% of the top- k lists that stem from $sum(A+B)$ queries, while only two query executions are required for 14% of the top- k lists. Similarly, 65% and 70% of the top- k lists from $max(A)$ queries are found after a single candidate query is executed, while 26.6% and 16% after two query executions, for TPC-H and SSB respectively. Moreover, as shown in Figures 5 and 6, ranked validation outperforms the expected unordered validation and the benefit increases with predicate size. The expected number of query validations reflects the case of executing candidate queries in random order. Assuming a uniform probability of the location of the valid queries in the candidate list, we compute the number of expected validations with dividing the number of candidate queries with the number of valid queries.

Query discovery efficiency. We study the efficiency of the different steps from our system. Figure 7 shows the runtime of each step of our approach. As expected, the total runtime is dominated by the database-related operation, i.e., the candidate query validation (Step 3). Note that Figure 7 shows the runtime of finding the first valid query. We observe that for the TPC-H dataset the runtime of Step 3 is orders of magnitude higher than that of Step 1 and 2. Thus, for max queries the average runtime of candidate query validation is 3.6 seconds, while the average runtime of identifying candidate predicates and ranking criteria is 12.4 and 3.9 milliseconds, respectively. With the SSB dataset and the same

Figure 7: Running times by step

Figure 8: Number of candidate predicates for $\max(A)$ queries

type of queries, Step 3 needs 7.5 seconds, while the runtime of Step 1 and 2 amounts to 3.3 and 0.3 seconds respectively. The table R from the SSB dataset has more tuples per entity, which leads to having a larger R' and more data to process with our algorithms.

Identifying candidate predicates. We study the effect of predicate size and the length of the input top- k lists on creating candidate predicates. Figure 8 shows the number of created candidate predicates with different predicate and input list size. We observe that for the TPC-H data, the average number of created candidate predicates increases from 13.8 with $|P| = 1$, to 69 with $|P| = 2$, and to 95 with $|P| = 3$. We observe the same trend with the SSB dataset. Larger predicate size leads to generating more candidate predicates. The reason for this is that for a valid predicate with size $|P|$ we create as candidate predicates all sub-predicates with size smaller than $|P|$ as well. The number of shared tuple sets is smaller than the one of created predicates.

Figure 8(b) shows the average number of created predicates with different length of the top- k input lists. We observe that the number of candidate predicates decreases with larger k . For TPC-H, the number of created predicates decreases from 41.3 for $k = 5$ to 14.3 for $k = 100$. With SSB, the average number of candidate predicates decreases from 1142.9 for $k = 5$ to 279.7 for $k = 100$. Larger k reduces the number of false positives in the candidate predicates. A predicate needs to select tuples with the distinct entities from the input list in order to qualify as a candidate predicate. With larger lists the number of entities increases, thus making it more difficult for a predicate to qualify as a candidate. Furthermore, we observe that a significantly larger number of predicates is created with the SSB data. This is due to the characteristics of the dataset, with SSB having more tuples per entity and more variety in data.

8.1 Evaluation with Sampling

The TPC-H generator creates uniform column distributions, thus the generated instance does not contain enough tuples per entity, with 14 tuples for an entity, at most. The

Figure 9: Valid query discovery with $\text{sum}(A+B)$ queries

SSB data has many tuples per entity, however these are extremely diverse in terms of predicates, i.e., the predicates found in the SSB queries often cover only a single tuple per entity. We thus focus on TPC-H data when employing sampling. There, for each tuple t in R we add n additional tuples, where n is a random number following the Gaussian distribution $\mathcal{N}(200, 50)$. These n tuples have the same values in the textual columns as t , but with non-key numerical values: $v = v + v \times \text{abs}(m)$, where $m \in [0, 1]$ is a random number following $\mathcal{N}(0.5, 0.5)$.

We study the effect of the sample size on the successful discovery of valid queries. We observe that a valid query is successfully discovered for **all** top- k lists that stem from single column queries, regardless of sample and predicate size. Figure 9 shows results for the discovery of $\text{sum}(A+B)$ queries. The discovery of valid queries depends on both the sample and predicate size. Having larger sample size enables better query discovery. For $|P| = 2$ and a sample size of 5% our system successfully manages to discover a valid query for 70% of the top- k lists. With a sample size of 10% the percentage of discovered queries increases to 85%, while with a sample size of 20% and larger, we manage to discover 100% of the queries with $|P| = 2$. Furthermore, we observe that discovering queries with larger predicate size is more difficult. With a sample size of 10% we successfully discover a valid query for 90% of the top- k lists with $|P| = 1$, 85% with $|P| = 2$, and 60% with $|P| = 3$. Queries with larger predicates are very selective, hence the probability of sampling tuples with a valid predicate is lower, which leads to false negatives. Sampling more tuples for these queries mediates this problem.

Smart Query Validation. Validating the created candidate queries is the bottleneck of our approach; executing (aggregated) queries on the database is expensive. We study the effects of our candidate query validation in terms of the computed query suitability and our result driven optimization. In addition, we investigate the effects of the predicate and sample size. Table 7 shows the average number of query executions needed using the two approaches for candidate query validation: smart result driven validation and ranked validation by query suitability. Furthermore, it shows the average number of created candidate queries Q_c for each query type and the average number of valid queries identified when having all tuples from R' available.

Figure 10 compares average number of executed queries with our two approaches to validation with the expected number of query validations if the candidate queries are not ordered. For $\max(A)$ queries, we observe that smart validation outperforms unordered validation by a factor of 7.3 with $|P| = 1$, 4.2 with $|P| = 2$, and 3.3 with $|P| = 3$. Furthermore, smart validation performs 26% query executions less than ranked validation with $|P| = 2$ and 33% less executions for $|P| = 3$. The benefits with discovering $\text{sum}(A+B)$ queries are even greater. Thus, smart validation in average reduces the number of expected query executions by a fac-

P	Sample %	select A_e , $\max(A)$				select A_e , $\sum(A + B)$

Table 7: Number of candidate query validations with the different approaches by sample and predicate size for $\max(A)$ and $\sum(A + B)$ queries

Figure 10: Number of query executions until first valid query with 30% sample for TPC-H data

tor of 424.7 with $|P| = 1$, 124.7 with $|P| = 2$, and 192.6 with $|P| = 3$. The greater benefit with this type of queries stems from the fact that identifying the ranking criteria involves different combinations of columns, which significantly increases the number of candidate queries.

Furthermore, smart validation significantly outperforms ranked validation with smaller sample size. Thus, with sample size of 5% smart validation reduces the number of query executions for discovering $\sum(A+B)$ queries over the rank-based validation by a factor of 13.7 and 12.6, with $|P| = 2$ and $|P| = 3$ respectively. Similarly, with a sample size of 10% smart validation reduces the average number of executions by a factor of 20.2 with $|P| = 2$ and 7.3 with $|P| = 3$. We observe that smart candidate query validation improves over rank-based validation for $\max(A)$ queries as well, albeit with smaller but still significant effect. The greater benefit with $\sum(A+B)$ queries stems from the fact that identifying the ranking criteria is more complex with this type of queries, thus making the query suitability less precise.

Larger sample size improves the candidate query suitability and reduces the number of candidate queries, thus resulting in less query validations. Smart validation reduces the number of validations for discovering $\max(A)$ queries with a sample size of 30% by an average factor of 4.6 over a sample of 5%. Less candidate queries are created with larger sample size, since the availability of more tuples leads to better generation of candidate predicates and we discuss this later using Figure 11. Larger sample size significantly improves the approximation in finding the ranking criteria with $\sum(A+B)$ queries and the factor of improvement amounts to 8.8 for the same sample sizes.

Larger predicate size increases the number of needed query validations. We observe that with a sample size of 30% discovering $\max(A)$ queries requires 3.6 candidate query val-

idations with $|P| = 1$, 6.4 with $|P| = 2$, and 20.3 with $|P| = 3$. With the same sample size, discovering $\sum(A+B)$ queries needs 4.3, 10.5, and 15.4 query executions, with $|P| = 1$, $|P| = 2$, and $|P| = 3$ respectively. Queries with larger predicates are more selective, thus it is less probable that tuples selected by the valid predicate will be sampled. Additionally, subpredicates of a larger valid predicate can select the same tuples as the larger predicate, but in turn the smaller predicates are less selective which reduces their probability of being a false positive. Hence, candidate queries with smaller predicates can have higher query suitability.

Note that with sampling, the number of candidate queries for $\max(A)$ queries is significantly lower than that of $\sum(A+B)$ queries, as shown in Table 7. With single column queries identifying the ranking criteria is an easier task and we can limit the number of columns to consider as candidates. With $\sum(A+B)$ queries on the other hand, the task of finding the ranking criteria involves combinations of two columns, thus making it more complicated. Furthermore, it is difficult to limit the number of column combinations to consider since a certain column with very large numbers (e.g., *total_price* in TPC-H) can dominate the sum. Hence, we consider all possible column combinations as candidate ranking criteria and rank them according to their approximated L1 distance.

Identifying Candidate Predicates. We study the effect of sample size on the number of created candidate predicates. We observe that the number of candidate predicates decreases with larger sample size. Larger sample size increases the probability of sampling larger number of tuples with a valid predicate, which in turn allows for stricter criteria in qualifying a predicate as candidate. Following the sampling probability in Section 6, with larger sample size we increased the ratio of covered entities in order to denote a predicate as a candidate. Thus, for sample size of 5%, the ratio of covered entities was set to 0.5, for 10% to 0.6, for 20% to 0.7, and to 0.8 for a sample size of 30%. Lower ratio avoids false negatives, but comes at the cost of increasing the number of false positives, since more predicates will qualify as candidates.

It is important to note that the experiments with sampling introduced expected variability. Depending on which tuples are sampled, the probability of the candidate predicates varies. Furthermore identifying the ranking criteria with $\sum(A+B)$ queries is influenced by the sampled tuples. **Example:** We ran five executions of the input list from the second query in Table 6 with $k = 10$ and sample of 5%. As a best case a valid query is found after only 2 query execution, while 125 executed candidate queries were needed

Figure 11: Number of candidate predicates for $\max(A)$ queries

in the worst case. In the first case, the sampled rows contain the correct predicate for each distinct entity, i.e., the predicate probability is 1.0. Additionally, the correct ranking criteria (column combination) has the second lowest L1 distance on the valid predicate. It seems that the sampled rows were good for approximating the ranking values for the correct columns. In the other case, the predicate probability is 0.84 (14th in the ranking), while the correct column combination has a very large L1 distance, since the sampled tuples were not a good approximation of the ranking values. The remaining executions resulted in 27, 16, and 39 query validations. With smaller sample size it is more difficult to find the ranking criteria for $\text{sum}(A + B)$ queries. This is a consequence of the non-uniform distribution of the values in A and B . Thus, the approximation depends on which tuples are sampled. Larger sample size mediates this problem. Having more tuples avoids the dependence on which tuples are sampled and leads to a more precise approximation.

8.2 Lessons Learned

With all tuples from R' available our system **always** discovers a valid query. Furthermore, for both datasets this is done efficiently and requires just a few query executions with only a single query validation for 76% and 68% of the top-k lists that stem from $\text{sum}(A + B)$ and $\max(A)$ queries, respectively. On the other hand, sampling introduces the possibility of false negatives. However, we manage to discover a valid query for all top-k lists that result from a single column query. Finding valid $\text{sum}(A + B)$ queries is more difficult and we manage to identify a valid query for 96.7% of the top-k lists with a sample size of 30%. Identifying the candidate predicates and ranking criteria is done in-memory and are very efficient. The smart result driven candidate query validation significantly reduces the number of query executions needed in finding a valid query. In addition, larger predicate size leads to more query validations. Larger sample size reduces both the number of false positives and false negatives in the candidate predicates. Furthermore, having more data improves the ranking of the candidate ranking criteria, since we have better approximation of the L1 distance.

9. CONCLUSION AND OUTLOOK

We proposed a framework to reverse engineer top-k OLAP queries. This has turned out a complex problem given the various dimensions of the search space, the potentially very large base relation, and the small input snippet in form of a top-k list. Our approach mainly operates on a subset of the base relation, held in memory, and further uses data samples, histograms, and simple descriptive statistics to identify potentially valid queries (that generate the input list). We proposed a probabilistic model that evaluates the suitability of a query discovered over a subset of R' , methodology that is directly applicable to the case of handling variations of R and considering partial match queries, i.e., queries that only

approximately match the input list. In any case, when trying to identify promising queries, the main difficulty is to limit the number of false positives—that cause unnecessary query validations—as well as to limit false negatives—that cause loss in recall. The ordering of potentially valid queries according to the probabilistic model in addition to an iterative refinement of the validation of candidate queries was proven to drastically decrease the amount of time to validate (or invalidate) queries in the final stage of the approach. This is specifically true for cases of low sampling rates—and expectedly likewise for partial-match scenarios.

As ongoing work, we investigate whether existing work on reverse engineering *join queries* is compatible with our approach and evaluate PALEO in partial-match scenarios.

ABSTRACT

In this paper, we propose a crowdsourcing-based approach to solving skyline queries with incomplete data. Our main idea is to leverage crowds to infer the pair-wise preferences between tuples when the values of tuples in some attributes are unknown. Specifically, our proposed solution considers three key factors used in existing crowd-enabled algorithms: (1) minimizing a *monetary cost* in identifying a crowdsourced skyline by using a *dominating set*, (2) reducing the number of rounds for *latency* by parallelizing the questions asked to crowds, and (3) improving the *accuracy* of a crowdsourced skyline by dynamically assigning the number of crowd workers per question. We evaluate our solution over both simulated and real crowdsourcing using the Amazon Mechanical Turk. Compared to a sort-based baseline method, our solution significantly minimizes the monetary cost, and reduces the number of rounds up to two orders of magnitude. In addition, our dynamic majority voting method shows higher accuracy than both static majority voting method and the existing solution using unary questions.

1. INTRODUCTION

In recent years, crowdsourcing has become a new paradigm for implementing human computation. Many extensions to existing DBMS techniques have been proposed to employ crowdsourcing so that the problems difficult for machines but easier for humans can be solved better than ever, *e.g.*, CrowdDB [5], Qurk [13], Deco [19], AskIt! [1], and CyLog/Crowd4U [16]. Motivated by their success, ones attempt to leverage crowdsourcing into existing micro-level query operations. For instance, they are selection [6, 18, 21], join [14, 24, 25, 26], group-by [4], max [8, 22, 23], and sort [14].

In this paper, we study a crowdsourcing-based approach to solving *skyline queries* with incomplete data. The skyline queries have gained considerable attention for assisting multi-criteria decision making applications [2, 9, 17]. Given two tuples s and t , it is said that s *dominates* t if the values of s are no worse than those of t over all attributes and the values of s are better than those of t over any attribute. Given a set \mathcal{R} of tuples, the *skyline* is a set of tuples that are not dominated by any other tuples in \mathcal{R} . To illustrate this, we consider the following motivating example.

EXAMPLE 1 (SKYLINE QUERY) Suppose that Alice wants to find the skyline movies of her preference, *i.e.*, most popular and most romantic movies, released in 2010-2015.

```
SELECT * FROM movie_db
WHERE year >= 2010 and year <= 2015
SKYLINE OF box_office MAX, romantic MAX
```

The popularity can be estimated by the *box_office* (*i.e.*, the number of movie audiences) attribute. However, the *movie_db* table does not record how romantic a movie is. That is, in the *romantic* attribute, the values of tuples are all unknown (or missing). To address this problem, we utilize crowdsourcing that can effectively infer missing values on the subjective attribute. Specifically, we ask crowds which movie is more *romantic* with respect to two movies, and get a relative preference of movies by using a *pair-wise question*. By repeatedly asking such pair-wise questions and aggregating their answers, we can fill missing values of tuples, and then find a skyline. Note that our setting above is an extreme case (*i.e.*, all values of tuples are missing in the *romantic* attribute). When some values of tuples are missing, we can apply our proposed solution to only the tuples with missing values. □

A *crowd-enabled skyline query* is defined as a skyline query with incomplete data in which crowds are used to infer the missing preferences between tuples [12]. Although existing work [12] addresses crowd-enabled skyline queries, it assumes a fixed budget and computes a *probabilistic* skyline. In contrast, our goal is minimize the number of pair-wise questions to crowds in identifying a *complete* skyline. In addition, [12] is based on *unary* questions to assess missing values of tuples. Because it is difficult to obtain correct answers for unary questions, the skyline result in [12] can be inaccurate. In our empirical study, it is observed that the pair-wise questions achieve higher accuracy than the unary questions in existing work [12].

In order to address skyline queries with crowdsourcing, we deal with three key factors: (1) how to minimize rewards paid to crowds (*i.e.*, *monetary cost*), (2) how to reduce the delay of crowd-enabled computation (*i.e.*, *latency*), and (3) how to improve the quality of the skyline using the answers obtained from crowds (*i.e.*, *accuracy*). When asking questions to crowds, we have to pay certain monetary rewards. Assuming that a fixed amount of a reward per question is paid, the monetary cost is proportional to the number of questions asked to crowds. In order to measure the latency, we need to estimate the running time to obtain answers from crowds in a *round*. Assuming that each round has a fixed amount of time [25], the latency is proportional to the number of rounds needed for asking all questions.

We then propose a new solution that addresses crowd-enabled skyline queries for each factor. First, in order to minimize the monetary cost, it is essential to remove unnecessary questions while

computing a crowdsourced skyline. Toward this goal, we make use of two relationships between tuples, *dominance* and *incomparability*. In particular, we adopt a *dominating set* to remove unnecessary questions in identifying a skyline. That is, given a tuple t , the dominating set $DS(t)$ is a set of tuples that dominate t . Using $DS(t)$, we can skip the questions for tuples with the *incomparability* relationship, and selectively ask the questions for tuples with the *dominance* relationships. We also prune unnecessary questions by using the *transitivity* of dominance relationships in $DS(t)$.

Second, we address how to reduce the number of rounds by asking multiple *independent* questions in a round. A set of questions are said to be independent if the answers of each question do not affect the other questions in the set. We show that independent questions can be asked in a round, yielding the *parallelization* of asking questions. Based on this observation, we develop two parallelization methods that significantly reduce the number of rounds without influencing other factors.

Lastly, we explain how to improve the accuracy of a crowd-sourced skyline. When a single crowd worker is assigned per question, some answers can be erroneous as workers can make mistakes. To alleviate this problem, we assign multiple workers per question and decide the final answer by using *majority voting* [6, 11, 15, 18]. As the simplest method, we can *equally* assign the same number of workers for each question. Because it neglects the characteristics of skyline queries, however, we develop a *dynamic* assignment strategy in which the number of workers can be assigned differently depending on the *importance* of questions. The proposed dynamic assignment can improve the accuracy of the crowdsourced skyline without incurring additional monetary cost.

To summarize, our main contributions are as follows:

- We formulate the problem of crowd-enabled skyline queries with three key factors used in crowd-enabled algorithms.
- To minimize monetary cost, we propose a crowd-enabled skyline algorithm with three pruning methods on top of the notion of a dominating set.
- To reduce the number of rounds, we develop two parallelization methods based on the notion of dominating sets and skyline layers.
- To improve the accuracy of the crowdsourced skyline, we design a dynamic majority voting that assigns the number of workers depending on the importance of questions.
- We validate the effectiveness of our proposed algorithm in both simulated and real-life crowdsourcing using the Amazon Mechanical Turk. In terms of accuracy, we also compare our proposed solution against existing work [12].

The remainder of this paper is organized as follows. In Section 2, we explain the concept of crowd-enabled algorithms and formulate the skyline query with crowdsourcing. In Section 3, we first propose an algorithm to minimize monetary cost using several pruning methods. In Section 4, we develop two algorithms to minimize the number of rounds by parallelizing multiple questions in a round. In Section 5, we design a dynamic majority voting that improves a static majority voting by considering the importance of questions. In Section 6, we empirically compare our proposed algorithm with the baseline and existing crowdsourced skyline algorithms with unary questions. In Section 7, we review our related work. In Section 8, we summarize and conclude our work.

2. PRELIMINARIES

In this section, we first present the concept of crowd-enabled algorithms (Section 2.1), and then explain the basic notion of skyline queries (Section 2.2). We lastly formulate the problem of skyline queries with crowdsourcing, where questions are asked to crowds to acquire the relative preferences between tuples with missing values (Section 2.3).

2.1 Crowd-Enabled Algorithms

The crowd-enabled algorithms first require us to design the format of *micro-tasks* asked to crowds. Because the micro-tasks are typically represented as *questions*, we use both terms, micro-tasks and questions, interchangeably. Let π denote a *latent scoring function* with which crowds assess the missing value of a tuple. The argument of π can differ depending on formats of questions.

Specifically, the micro-tasks are classified into *quantitative* and *qualitative* formats [14]. First, the quantitative format asks crowds to determine an *absolute* (normalized) preference. This can be abstracted as a *unary function* $\pi(t)$ for a tuple t , e.g., rating from 1 to 7 for the size of a given square. Let n denote the number of tuples with missing values. While the unary function is effective for minimizing the number of questions in determining the total order of tuples, i.e., n questions, the accuracy of answers can be low. That is, because crowds usually have no *global* knowledge for missing values of tuples, it is difficult for them to return correct answers.

Second, the qualitative format allows crowds to judge the *relative* preference between two (or more) tuples. As the simplest format, it can be modeled as a *binary function* $\pi(s, t)$ to compare two tuples s and t , e.g., selecting one with a larger size between two squares. (Possibly, it can be extended to an m -ary format.) Compared to the quantitative format, because it only requires relative preference between two tuples, more questions are usually asked. In the worst case, $\binom{n}{2}$ questions are needed for obtaining a total order of n tuples. Meanwhile, because the crowd can answer binary questions correctly without global knowledge for missing values, the accuracy of answers in the qualitative format is higher than that in the quantitative format.

In this paper, we adopt binary function $\pi(s, t)$ for questions in order to obtain more accurate answers. That is, we use a *pair-wise question* (s, t) with *ternary* answers, where it is *symmetric*, i.e., $\pi(s, t) = \pi(t, s)$. Given (s, t) , the crowd chooses a *more* preferred one (i.e., either s or t) or the third option, indicating that the two tuples are *equally* preferred. For example, the following questions are asked to crowds: “which square between the two is larger?” or “who is a more valuable baseball player?”

We next explain three key factors used in existing crowd-enabled algorithms, e.g., [4, 6, 18, 20, 22, 25]. Using the key factors, we formulate the problem of crowd-enabled skyline queries (Section 2.3).

(1) **Monetary cost:** Unlike existing machine-only algorithms, crowd-enabled algorithms compensate rewards to crowds. Assuming that a fixed amount of a reward per question is paid, the monetary cost is proportional to the number of questions asked to crowds. For monetary cost, there are two optimization directions: (1) minimizing the number of questions asked for obtaining a complete query result and (2) selecting the most important questions for a given budget. In this paper, we focus on minimizing the total number of questions during executing a skyline query with crowdsourcing.

(2) **Latency:** Since each question can take different time to finish, it is non-trivial to design an effective model for estimating latency. As an alternative way, we assume that a fixed amount of time is assigned per question. Because multiple questions can be performed in parallel, we use the number of *rounds* (or *iterations*.) to measure

the latency [25]. Specifically, there are two strategies in latency: (1) *one-shot strategy* that generates all questions at once, and (2) *adaptive strategy* that asks questions in an interactive manner. Because the one-shot strategy needs only one round, it is much faster than the adaptive strategy. Meanwhile, the adaptive strategy can identify unnecessary questions by using the answers of questions asked at the previous rounds, and thus reduces the total number of questions. In this paper, we leverage the adaptive strategy and discuss how to minimize the latency for a given question set.

(3) **Accuracy:** Because crowds can make mistakes in answering questions, the accuracy of a query result can be imperfect. There are two models to improve the accuracy: *query-independent* and *query-dependent* models. Existing work [6, 11, 15, 18] proposed various query-independent methods to improve the accuracy for a single question by considering the proficiency of workers and the difficulty of questions. Although improving the accuracy of a query result in a micro-level manner, they do not consider the *importance* of questions depending on an inherent property of a query type in a macro-level way, e.g., [4, 20]. In this paper, we aim to develop a query-dependent method by distinguishing the importance of questions for a skyline query.

2.2 Skyline Queries with Missing Data

Let \mathcal{A} denote a finite set of d attributes, $\mathcal{A} = \{A_1, \dots, A_d\}$, in which the domain D_i of A_i is a set of positive numbers and a *missing value*, denoted by \square , i.e., $D_i := \mathbb{R}^+ \cup \{\square\}$. A base dataset \mathcal{R} is an instance of database relations, i.e., $\mathcal{R} \subseteq D_1 \times \dots \times D_d$. Each tuple $t \in \mathcal{R}$ is represented by $t = (t_1, \dots, t_d)$ such that $t_i \in D_i$ for $i = 1, \dots, d$. In this paper, we use s , t , u , and v to point out arbitrary tuples.

The attribute set \mathcal{A} is divided into two attribute subsets. First, \mathcal{A}^K is a set of attributes in which the values of tuples are *known*. The preference of values over \mathcal{A}^K can be represented by a total order. Second, \mathcal{A}^C is a subset of attributes in \mathcal{A} , where the values of tuples are *missing*. We call \mathcal{A}^C *crowd attributes*. Two attribute sets are *disjoint*, i.e., $\mathcal{A}^K \cap \mathcal{A}^C = \emptyset$, $\mathcal{A}^K \cup \mathcal{A}^C = \mathcal{A}$. We assume that all values of tuples in \mathcal{A}^C are missing, i.e., *hand-off crowdsourcing* [7]. That is, for any tuple $t \in \mathcal{R}$, $\forall A_j \in \mathcal{A}^C : t_j = \square$ holds. This implies that all preferences between tuples in \mathcal{A}^C should be assessed by crowds. After the missing preferences between tuples in \mathcal{A}^C are judged by crowds, it can be represented by a *partial* order of tuples. When a subset of tuples in \mathcal{R} only has missing values in many real applications, some known values of tuples can be represented by a pre-defined partial order. Therefore, we can extend our proposed techniques for real-life scenarios.

We next define fundamental notions used in skyline literatures [2, 9, 17]. In this paper, we assume that smaller values over \mathcal{A}^K are more preferred. Given $s, t \in \mathcal{R}$, a *strict preference* $s <_i t$ is defined if s is preferred over t in A_i . Let $s \lesssim_i t$ define a *weak preference* if $s <_i t$ or $s =_i t$ in A_i . If no preference between s and t is inferred in $A_i \in \mathcal{A}^C$, an *indifferent preference* $s \perp_i t$ is defined.

DEFINITION 1 (DOMINANCE) Given $s, t \in \mathcal{R}$, s *dominates* t in \mathcal{A} , denoted by $s \prec_{\mathcal{A}} t$, if $\forall A_i \in \mathcal{A} : s \lesssim_i t$ and $\exists A_j \in \mathcal{A} : s <_j t$. If s does not dominate t in \mathcal{A} , it is denoted as $s \not\prec_{\mathcal{A}} t$.

DEFINITION 2 (INCOMPARABILITY) Given $s, t \in \mathcal{R}$, they are *incomparable* in \mathcal{A} , denoted by $s \not\prec_{\mathcal{A}} t$, if (i) $s \not\prec_{\mathcal{A}} t$ and $t \not\prec_{\mathcal{A}} s$ or (ii) $\exists A_j \in \mathcal{A}^C : s \perp_j t$.

DEFINITION 3 (SKYLINE) Given a set \mathcal{R} of tuples, a *skyline* is a set of tuples that are not dominated by any other tuples in \mathcal{A} , i.e., $\text{SKY}_{\mathcal{A}}(\mathcal{R}) = \{t \in \mathcal{R} | \forall s \in \mathcal{R} : s \not\prec_{\mathcal{A}} t\}$.

Figure 1: A toy dataset for a crowdsourced skyline query with $\mathcal{A} = \{A_1, A_2, A_3\}$

These notions can be applied to a subset of \mathcal{A} . That is, \mathcal{A} in $\prec_{\mathcal{A}}$, $\not\prec_{\mathcal{A}}$, and $\not\succ_{\mathcal{A}}$ can be replaced with \mathcal{A}^K or \mathcal{A}^C .

2.3 Problem Formulation

The earlier work [12] maximized the accuracy of the crowd-sourced skyline at a fixed budget. When tuples have missing values, [12] adopts crowds to assess missing values of tuples with a unary question. In contrast to [12], in order to achieve more reliable skyline results, our goal is to minimize monetary cost while computing crowd-enabled skyline queries in which binary questions are used for obtaining the preferences between tuples. (In Section 7, we explain the differences between ours and [12].)

When the crowds evaluate missing values of tuples, a skyline result can be iteratively updated. Initially, since the preferences of tuples over \mathcal{A}^C are undefined, all tuples are incomparable to each other, and by default in the skyline. Let $Q(t) = \{(s, t) | s \in \mathcal{R} \setminus \{t\}\}$ be a set of all possible pair-wise questions for t . After a question set $Q'(t) \subseteq Q(t)$ is answered by crowds, s can exist such that $s \prec_{\mathcal{A}} t$. At this point, t becomes a non-skyline tuple, and is removed from the initial skyline. If the status of t is not changed regardless of remaining questions for t , it is called a *complete* tuple. That is, once t is determined as a complete tuple, additional questions for t are *unnecessary*.

DEFINITION 4 (COMPLETE TUPLE) After a set of questions $Q'(t) \subseteq Q(t)$ is answered, a tuple t is said to be *complete* if (i) $\exists s \in \mathcal{R} : s \prec_{\mathcal{A}} t$, (i.e., a *complete non-skyline tuple*) or (ii) $\forall s \in \mathcal{R} : s \not\prec_{\mathcal{A}} t$ holds regardless of the answers of remaining questions $Q(t) - Q'(t)$ for t , (i.e., a *complete skyline tuple*).

EXAMPLE 2 (CROWD-ENABLED SKYLINE QUERY) Given a set \mathcal{R} of 12 tuples, Figure 1 depicts a toy dataset for a crowd-enabled skyline query such that $\mathcal{A}^K = \{A_1, A_2\}$ and $\mathcal{A}^C = \{A_3\}$. Note that all values of \mathcal{R} in A_3 are missing. Since $\{b, e, i, l\}$ (a dashed line in Figure 1a) are not dominated by any other tuples in \mathcal{A}^K , they are always in the skyline in \mathcal{A} regardless of preferences of tuples in \mathcal{A}^C . Therefore, they are complete skyline tuples. Because the other tuples can be non-skyline tuples depending on the results of questions on \mathcal{A}^C , however, they are regarded to be incomplete tuples. Suppose that the preferences of tuples in \mathcal{A}^C are depicted in Figure 1(b), where an edge $s \rightarrow t$ indicates that s is preferred over t in \mathcal{A}^C and transitivity between edges holds. (In Section 3.3, we discuss how to build a preference tree in \mathcal{A}^C .) Since $b \prec_{\mathcal{A}^K} a$ and $b \prec_{\mathcal{A}^C} a$, a becomes a non-skyline tuple. By using the preference relationships in Figure 1(b), all tuples become complete tuples, and the skyline is finally identified as $\{b, e, i, l, k, f, h\}$. \square

In this paper, we consider three key factors, *i.e.*, monetary cost, latency, accuracy, in computing crowd-enabled skyline queries. We first aim to minimize the number of questions in identifying a complete skyline. Then, we further optimize the other factors for a given question set. Although this problem formulation does not identify a solution that optimizes three factors simultaneously, it can be a more practical setting as done in [24, 25]. Formally:

PROBLEM 1 (CROWDSOURCED SKYLINE) Let \mathcal{P} be a set of possible *execution plans* for computing a complete skyline. Our problem is to identify an execution plan $P_{opt} \in \mathcal{P}$ that minimizes monetary cost $C(P, \mathcal{R})$ for questions in \mathcal{A}^C .

$$P_{opt} = \operatorname{argmin}_{P \in \mathcal{P}} C(P, \mathcal{R})$$

Note that P_{opt} can also be used for optimizing the other factors such as latency and accuracy. ■

Assuming that a single question is asked at each round, execution plan P can be represented by a sequence set \mathcal{Q} of questions, *e.g.*, $\mathcal{Q} = \langle (a, b), \dots, (k, l) \rangle$. Let $|\mathcal{Q}|$ denote the number of questions in \mathcal{Q} . When the monetary cost per question is equal, $C(P, \mathcal{R})$ becomes proportional to $|\mathcal{Q}|$. Therefore, we minimize the number of questions $|\mathcal{Q}|$ in identifying a complete skyline tuple.

In the following sections, we first assume that the answers of crowds are always correct. Based on this assumption, we propose a crowd-enabled skyline algorithm to minimize $|\mathcal{Q}|$ (Section 3). When multiple questions are asked in parallel, we also develop how to reduce the number of rounds for \mathcal{Q} (Section 4). By relaxing such an assumption, we lastly discuss how to improve the accuracy of a complete skyline while both the number of questions and the latency are kept (Section 5).

3. MINIMIZING MONETARY COST

As a baseline method, we may ask all possible pair-wise questions between tuples, *i.e.*, $\binom{n}{2}$ to obtain the total order of tuples. However, because it is too exhaustive, we modify existing sorting algorithms such as *tournament sort* and *bitonic sort* [3] with crowdsourcing. Specifically, the pair-wise comparisons in existing sorting-based algorithms [3] can be replaced by binary questions, and the total order of tuples in \mathcal{A}^C can be used to identify a crowd-sourced skyline. While the sorting-based method is effective for obtaining all missing preferences of tuples, it can incur unnecessary questions in computing the crowd-enabled skyline.

To address this problem, it is observed that the *dominance* and *incomparability* relationships of tuples in \mathcal{A}^K can be used to reduce unnecessary questions. Based on this observation, we adopt the notion of a *dominating set* to remove unnecessary questions. In the following sections, we also develop several pruning methods on top of the dominance set to remove additional questions.

For a simpler presentation, when \mathcal{A}^C has multiple attributes, *i.e.*, $m = |\mathcal{A}^C| > 1$, we suppose that m questions for (s, t) are asked at once, *i.e.*, $\forall A_j \in \mathcal{A}^C : (s_j, t_j)$. Because m questions can be asked simultaneously, we simply use (s, t) to denote m questions for (s, t) , when context is clear.

In addition, we suppose that the values of tuples in \mathcal{A}^K are distinct, *i.e.*, for any tuples $s, t \in \mathcal{R}$, $\exists A_i \in \mathcal{A}^K : s_i \neq t_i$ holds. As a degenerate case, we separately handle a tuple set with the same values in \mathcal{A}^K . Because we cannot exploit our pruning methods for the tuple set, it is performed as a pre-processing step. That is, given (s, t) such that $\forall A_j \in \mathcal{A}^K : s_j = t_j$, we remove a non-skyline tuple by identifying the dominance relationship between two tuples in \mathcal{A}^C . (This degenerate case is described in lines 1–3 in Algo-

Table 1: Dominating sets and question sets for the toy dataset in Figure 1(a)

t	$DS(t)$	t	$Q(t)$
a	$\{b\}$	a	$\{(a, b)\}$
c	$\{a, b, e\}$	c	$\{(c, a), (c, b), (c, e)\}$
d	$\{b, e\}$	d	$\{(d, b), (d, e)\}$
f	$\{a, b, d, e\}$	f	$\{(f, a), (f, b), (f, d), (f, e)\}$
g	$\{e\}$	g	$\{(g, e)\}$
h	$\{b, d, e, g, i\}$	h	$\{(h, b), (h, d), (h, e), (h, g), (h, i)\}$
j	$\{a, b, d, e, f, g, h, i\}$	j	$\{(j, a), (j, b), (j, d), (j, e), (j, f), (j, g), (j, h), (j, i)\}$
k	$\{i, l\}$	k	$\{(k, i), (k, l)\}$

(a) Dominating sets

(b) Question sets

rithm 1.) After performing the pre-processing, we can safely make use of our pruning methods without loss of correctness.

3.1 Using a Dominating Set

We first exploit the incomparability relationship of tuples to bypass unnecessary questions. For instance, when two tuples $a = (2, 8, \square)$ and $d = (5, 7, \square)$ in Figure 1(a) are incomparable in $\mathcal{A}^K = \{A_1, A_2\}$, they also become incomparable in \mathcal{A} regardless of the answer of (a, d) in $\mathcal{A}^C = \{A_3\}$. That is, we only need to compare a question (s, t) in \mathcal{A}^C by asking a question (s, t) if s and t are *not incomparable* in \mathcal{A}^K by using the property of sharing incomparability [10].

Based on this property, we adopt a *dominating set* $DS(t)$ for a tuple $t \in \mathcal{R}$ as a set of candidates that can affect the dominance relationship of t in \mathcal{A} . That is, the dominance set ensures that only the questions $Q(t) = \{(s, t) | s \in DS(t)\}$ are enough to generate the dominance relationship between s and t in \mathcal{A} .

DEFINITION 5 (DOMINATING SET) A *dominating set* $DS(t)$ of a tuple $t \in \mathcal{R}$ is a set of tuples that dominate t in \mathcal{A}^K , *i.e.*, $DS(t) = \{s \in \mathcal{R} | \forall s \in \mathcal{R} \setminus \{t\} : s \prec_{\mathcal{A}^K} t\}$.

LEMMA 1 Given $t \in \mathcal{R}$ and $s \notin DS(t)$, (s, t) is unnecessary in $Q(t)$.

PROOF. We prove this by contradiction. Assume that a question (s, t) exists that $s \notin DS(t)$ dominates t in \mathcal{A} . By Definition 5, $s \notin DS(t)$ does not dominate t in \mathcal{A}^K . Because $\mathcal{A}^K \subset \mathcal{A}$, s cannot dominate t in \mathcal{A} regardless of asking (s, t) . That is, we do not have to ask a question (s, t) to determine whether t is complete. This contradicts that asking question (s, t) is necessary for t to be complete.

EXAMPLE 3 (DOMINATING SET) Continue to use the toy dataset in Figure 1(a). Table 1(a) illustrates dominating sets for each tuple. The questions generated by dominating sets are shown in Table 1(b). As a result, the total number of questions (*i.e.*, 26 questions) is calculated as $\sum_{t \in \mathcal{R}} |DS(t)|$, where $|DS(t)|$ is the number of tuples in $DS(t)$. □

3.2 Pruning Questions for Non-skylines in \mathcal{A}

While sequentially generating (s, t) such that $s \in DS(t)$, t can be determined as a complete tuple (by Definition 4). For *all* of the questions, if t is preferred to s , t becomes a *complete skyline tuple*. On the other hand, if t is not preferred to s for *any* question, t becomes a *complete non-skyline tuple* and remaining questions in $Q(t)$ can be skipped. Once $s \prec_{\mathcal{A}} t$ is determined, it can also be used for removing additional unnecessary questions for any

Table 2: Sorted dominating sets and question sets after removing a (\emptyset), g (\emptyset), and d (\emptyset), respectively

t	$DS(t)$	t	$Q(t)$
a	$\{b\}$	a	$\{(a, b)\}$
g	$\{e\}$	g	$\{(g, e)\}$
d	$\{b, e\}$	d	$\{(d, b), (d, e)\}$
k	$\{i, l\}$	k	$\{(k, i), (k, l)\}$
c	$\{a, b, e\}$	c	$\{(c, a), (c, b), (c, e)\}$
f	$\{a, b, d, e\}$	f	$\{(f, a), (f, b), (f, d), (f, e)\}$
h	$\{b, d, e, g, i\}$	h	$\{(h, b), (h, d), (h, e), (h, g), (h, i)\}$
j	$\{a, b, d, e, f, g, h, i\}$	j	$\{(j, a), (j, b), (j, d), (j, e), (j, f), (j, g), (j, h), (j, i)\}$

(a) Sorted dominating sets

(b) Question sets

other tuple. That is, once a tuple t is determined as a complete non-skyline tuple, we can safely skip to ask all questions for t as unnecessary ones.

LEMMA 2 If $s \prec_{\mathcal{A}} u$ and $u \in DS(t)$ hold, then $s \in DS(t)$ also holds.

PROOF. By definition of $DS(t)$, $u \in DS(t) \Leftrightarrow u \prec_{\mathcal{A}^K} t$, and \mathcal{A} is divided to two subsets \mathcal{A}^K and \mathcal{A}^C . When $s \prec_{\mathcal{A}} u$, there are three cases:

1. $(s \prec_{\mathcal{A}^K} u) \wedge (s \prec_{\mathcal{A}^C} u)$: since $s \prec_{\mathcal{A}^K} u$ and $u \prec_{\mathcal{A}^K} t$ hold, $s \prec_{\mathcal{A}^K} t$ also holds by transitivity.
2. $(s \prec_{\mathcal{A}^K} u) \wedge (s =_{\mathcal{A}^C} u)$: since $s \prec_{\mathcal{A}^K} u$ and $u \prec_{\mathcal{A}^K} t$ hold, $s \prec_{\mathcal{A}^K} t$ also holds by transitivity.
3. $(s =_{\mathcal{A}^K} u) \wedge (s \prec_{\mathcal{A}^C} u)$: since $s =_{\mathcal{A}^K} u$ and $u \prec_{\mathcal{A}^K} t$ hold, $s \prec_{\mathcal{A}^K} t$ also holds.

In all cases, $s \prec_{\mathcal{A}^K} t$ always holds. By definition of $DS(u)$, $s \in DS(t)$ also holds.

COROLLARY 1 For a tuple $t \in \mathcal{R}$, if $s \prec_{\mathcal{A}} u$ and $u \in DS(t)$ hold, asking (t, u) is unnecessary in $Q(t)$.

PROOF When asking (s, t) , there exist two possible cases:

1. $s \prec_{\mathcal{A}^C} t$ or $s =_{\mathcal{A}^C} t$: By Lemma 2, $s \in DS(t)$ holds. Because $s \prec_{\mathcal{A}^K} t$, $s \prec_{\mathcal{A}} t$ holds. In that case, t becomes a complete non-skyline tuples regardless of asking (t, u) .
2. $t \prec_{\mathcal{A}^C} s$: Because $s \prec_{\mathcal{A}} u$, $u \not\prec_{\mathcal{A}^C} s$ holds. In that case, because $u \not\prec_{\mathcal{A}^C} t$ holds.

In both cases, asking (t, u) is unnecessary by asking (s, t) . ■

In order to remove unnecessary questions for non-skyline tuples by Corollary 1, it is essential to identify complete non-skyline tuples as many as possible. That is, it is *optimal* if $Q(t)$ is generated after all tuples in $DS(t)$ become complete. Toward this goal, we decide the ordering of evaluating tuples in an *iterative* manner. We first identify $\text{SKY}_{\mathcal{A}^K}(\mathcal{R})$ as complete tuples. Then, for a tuple $t \in \mathcal{R}$, we generate $Q(t)$ with the following steps: (1) If any tuple in $s \in DS(t)$ is a complete non-skyline tuple, s is removed from $DS(t)$; (2) If all tuples in $DS(t)$ are complete, $Q(t)$ is generated from $DS(t)$; (3) $Q(t)$ is asked until t is determined as a complete tuple; (4) The complete tuple set is updated by appending t . We repeat this process until all tuples become complete.

Figure 2: Preference tree \mathcal{T} in A_3 until evaluating h

We now propose an efficient method that performs the iterative strategy. Given two tuples s and t , $Q(s)$ has to precede $Q(t)$ if $s \in DS(t)$. It is found that this condition is always satisfied if tuples are evaluated by the ascending order of the size of dominating sets. That is, if $s \in DS(t)$, then $|DS(s)| < |DS(t)|$ holds, implying that the size of the dominating set increases monotonically if the dominance relationship between tuples holds. That is, given $s, t \in \mathcal{R}$, $Q(s)$ such that $s \in DS(t)$ is first asked before generating $Q(t)$. Formally:

LEMMA 3 Given $s, t \in \mathcal{R}$, if $|DS(t)| \geq |DS(s)|$, then $t \not\prec_{\mathcal{A}^K} s$ holds.

PROOF We prove this by contradiction. Assume that there are two tuples s and t such that $t \prec_{\mathcal{A}^K} s$ and $|DS(t)| \geq |DS(s)|$. Because $t \prec_{\mathcal{A}^K} s$, two conditions hold: (1) $t \in DS(s)$ and (2) $DS(t) \subseteq DS(s)$. By combining them, $|DS(t)| < |DS(s)|$ holds, which contradicts the fact that $|DS(t)| \geq |DS(s)|$. ■

EXAMPLE 4 (SORTING DOMINATING SETS) We continue to use the toy dataset used in Example 3. Table 2(a) shows the dominating sets sorted by $|DS(t)|$ in Table 1(a). According to the ordering of tuples in Table 2(a), the questions are sequentially generated from a to j . Assuming that $\{a, g, d\}$ have been determined as non-skyline tuples, Table 2(b) illustrates questions for each tuple. When (a, b) is asked and a is identified as a non-skyline tuple (i.e., $b \prec_{\mathcal{A}} a$), a is removed from $DS(c)$, $DS(f)$, and $DS(j)$. Similarly, after (g, e) is asked, if g is a non-skyline tuple, g is removed from $DS(h)$ and $DS(j)$. As a result, it only generates 18 questions by pruning 8 questions, i.e., $\{(c, a), (f, a), (j, a)\}$, $\{(h, g), (j, g)\}$, and $\{(f, d), (h, d), (j, d)\}$ for a, g , and d , respectively. □

3.3 Pruning Questions for Non-skylines in \mathcal{A}^C

When generating $Q(t)$ from $DS(t)$, we can further reduce $DS(t)$ to $\text{SKY}_{\mathcal{A}^C}(DS(t))$. For instance, after asking $\{(f, b), (f, e)\}$ for f , f has been determined as a complete skyline tuple, i.e., $f \prec_{\mathcal{A}^C} b$ and $f \prec_{\mathcal{A}^C} e$. In that case, the dominance relationship for f can be used for pruning questions for other tuples. For tuple j , $Q(j) = \{(j, b), (j, e), (j, f), (j, h), (j, i)\}$ for j is asked in Table 2(b). Because $f \prec_{\mathcal{A}^C} \{b, e\}$, it is better to ask (j, f) instead of asking (j, b) and (j, e) . If $j \prec_{\mathcal{A}^C} f$ is obtained, we can infer $j \prec_{\mathcal{A}^C} b$ and $j \prec_{\mathcal{A}^C} e$ by transitivity. Based on this property, we can skip two questions (j, b) and (j, e) for $Q(j)$.

LEMMA 4 For each tuple $s \in \text{SKY}_{\mathcal{A}^C}(DS(t))$, if $t \prec_{\mathcal{A}^C} s$ holds, then $t \prec_{\mathcal{A}^C} u$ such that $u \in (DS(t) - \text{SKY}_{\mathcal{A}^C}(DS(t)))$ holds.

PROOF. By Definition 3, there exists that $s \in \text{SKY}_{\mathcal{A}^C}(DS(t))$ dominates $u \in (DS(t) - \text{SKY}_{\mathcal{A}^C}(DS(t)))$ in \mathcal{A}^C . As a result, if $\forall s \in \text{SKY}_{\mathcal{A}^C}(DS(t)) : t \prec_{\mathcal{A}^C} s$ holds, $t \prec_{\mathcal{A}^C} u$ holds by transitivity.

Figure 3: An anti-correlated toy dataset for the crowd-enabled skyline query with $\mathcal{A} = \{A_1, A_2, A_3\}$

COROLLARY 2 Given $t \notin \text{SKY}_{\mathcal{A}^C}(DS(u))$, (t, u) is unnecessary in $Q(u)$.

PROOF For each $s \in \text{SKY}_{\mathcal{A}^C}(DS(u))$, if asking (s, u) , there are two cases:

1. $s \prec_{\mathcal{A}^C} u$ or $s =_{\mathcal{A}^C} u$: Because $s \prec_{\mathcal{A}^K} u$, $s \prec_{\mathcal{A}} u$ holds, and (t, u) is not needed.
2. $u \prec_{\mathcal{A}^C} s$: Because $s \prec_{\mathcal{A}^C} t$, u exists that $u \prec_{\mathcal{A}^C} t$ by Lemma 4.

In both cases, (t, u) is not needed by asking (s, u) . ■

We now adopt a *preference tree* \mathcal{T} that visualizes the preferences of tuples in \mathcal{A}^C in order to compute $\text{SKY}_{\mathcal{A}^C}(DS(t))$ efficiently. Each tuple $t \in \mathcal{R}$ is represented by a node in \mathcal{T} . If $s \prec_{\mathcal{A}^C} t$ holds, an edge $s \rightarrow t$ exists. If there exists a path from s to t connected with multiple edges, then $s \prec_{\mathcal{A}^C} t$ also holds by transitivity. If $s \not\prec_{\mathcal{A}^C} t$, there is no edge between s and t . After asking each question, \mathcal{T} is iteratively updated, and is used for identifying the dominance relationships by checking the path between tuples.

EXAMPLE 5 (USING A PREFERENCE TREE) Continuing from Example 4, Figure 2 depicts a snapshot of \mathcal{T} after evaluating h in A_3 . After removing non-skyline tuples, $DS(j)$ is $\{b, e, f, h, i\}$. By checking the dominance relationships between tuples in $DS(j)$, $f \prec_{\mathcal{A}^C} b$, $f \prec_{\mathcal{A}^C} e$, and $h \prec_{\mathcal{A}^C} i$ can be found in \mathcal{T} . Therefore, $\text{SKY}_{\mathcal{A}^C}(DS(j))$ is identified as $\{f, h\}$, and only $Q(j) = \{(j, f), (j, h)\}$ is asked in Table 2(b). □

3.4 Probing Dominating Sets

In general, our pruning methods of Corollaries 1 and 2 are more effective if: (1) many tuples are determined as complete non-skyline tuples, and (2) many dominance relationships between tuples are inferred in \mathcal{A}^C . However, we observe that the pruning methods may not work well if many non-skyline tuples in \mathcal{A}^K become skyline tuples in \mathcal{A} , e.g., anti-correlated distribution. Figure 3(a) illustrates a dataset with 10 tuples in $\mathcal{A}^K = \{A_1, A_2\}$. This can be partitioned to two subsets $\{b, e, i, j\}$ and $\{a, c, f, d, g, h\}$, i.e., the former is skyline tuples in \mathcal{A}^K , while the latter is non-skyline tuples in \mathcal{A}^K . When all non-skyline tuples become skyline tuples, our pruning methods cannot contribute to reduce the dominating sets of $\{a, c, f, d, g, h\}$. Thus, we have to ask a total of 24 ($= 4 \times 6$) questions to crowds.

Figure 4: Overall procedure of probing dominating sets

To overcome this problem, we progressively probe $DS(t)$ for t to minimize $\text{SKY}_{\mathcal{A}^C}(DS(t))$. Specifically, in asking questions for $\{b, e, i, j\}$, the dominance relationship can be used for reducing the dominance sets of $\{a, c, f, d, g, h\}$. For instance, suppose that the dominance relationships for $\{b, e, i, j\}$ in Figure 3(b) are updated after asking $\{(b, e), (i, j), (e, i)\}$. Since e dominates $\{b, i, j\}$ in \mathcal{A}^C , each single question for each tuple in $\{a, c, f, d, g, h\}$ are generated, i.e., $\{(e, a), (e, c), (e, f), (e, d), (e, g), (e, h)\}$. As a result, our probing method for $DS(t)$ enables us to only ask 9 ($= 3 + 6$) questions.

We now discuss how to generate questions for probing $DS(t)$. Given $DS(t)$, the number of possible questions is $\binom{|DS(t)|}{2}$. Because all possible ordering in probing $DS(t)$ is exponential and the dominance relationships of tuples in $DS(t)$ are unpredictable, it is non-trivial to decide the right ordering of probing $DS(t)$. As one of feasible solutions, we propose a *greedy* method using the *frequency* of dominating tuples. Let $P(t)$ denote a set of all possible questions $\binom{|DS(t)|}{2}$ for probing $DS(t)$. For each question (u, v) in $P(t)$, $\text{freq}(u, v)$ is the number of tuples that are dominated by both u and v , i.e., $\text{freq}(u, v) = |\{x \in \mathcal{R} | u \prec_{\mathcal{A}^K} x \wedge v \prec_{\mathcal{A}^K} x\}|$. As $\text{freq}(u, v)$ is higher, we suppose that the pruning power of (u, v) gets stronger. We choose the question with the highest frequency in $P(t)$, and remove the questions for less preferred tuples from $P(t)$. This process repeats until no questions exist in $P(t)$.

EXAMPLE 6 (PROBING DOMINATING SETS) The tuples are sorted by the size of dominating sets as shown in Table 2(a). For each tuple $t \in \mathcal{R}$, $DS(t)$ is first pruned by using the two pruning methods in Corollaries 1 and 2. We then probe $DS(t)$ before generating $Q(t)$. Figure 4(a) shows the questions asked per tuple. Before asking $Q(d)$, $P(d) = \{(b, e)\}$ is first probed. When $e \prec_{\mathcal{A}^C} b$ has been decided, b no longer needs to be compared, and thus the questions for b such as (c, b) , (f, b) , (h, b) , and (j, b) can be removed for c, f, h , and j , respectively. Figure 4(b) depicts a preference tree \mathcal{T} in A_3 after all tuples become complete. By probing dominating sets, we only ask 12 questions for identifying the final crowd-enabled skyline $\{b, e, i, l, k, f, h\}$. □

3.5 Algorithm Description

We present the pseudocode of our proposed algorithm, named **CrowdSky** (Algorithm 1). Overall, **CrowdSky** works as the combination of machine and crowds. That is, once the machine iteratively updates data structures and generates new questions, crowds return the answers. Specifically: (1) As a degenerate case, it first

Algorithm 1: CrowdSky(\mathcal{R})

```

2   if  $\forall A_j \in \mathcal{A}^K : s_i = t_i$  then
3     Ask  $(s, t)$  to crowds and remove a less preferred tuple from  $\mathcal{R}$ 
4 Initialize a preference tree  $\mathcal{T}$  in  $\mathcal{A}^C$ 
5 For each tuple  $t \in \mathcal{R}$ , compute  $DS(t)$ 
6  $\text{SKY}_{\mathcal{A}}(\mathcal{R}) \leftarrow \{\}$  // Initialize a skyline in  $\mathcal{A}$ 
  // P1: Early pruning for non-skylines in  $\mathcal{A}$ 
7 Sort  $\mathcal{R}$  by ascending order of  $|DS(t)|$ 
8 for  $t \in \mathcal{R}$  do
  // P2: Pruning non-skylines in  $\mathcal{A}^C$ 
9    $DS(t) \leftarrow \text{SKY}_{\mathcal{A}^C}(DS(t))$ 
  // P3: Probing into  $DS(t)$ 
10   $P(t) \leftarrow \{(u, v) | u, v \in DS(t), u \neq v\}$ 
11  Sort  $P(t)$  by ascending order of  $\text{freq}(u, v)$ 
12  for  $(u, v) \in P(t)$  do
13    Ask  $(u, v)$  to crowds, and update  $\mathcal{T}$  with  $(u, v)$ 
14    if  $u \prec_{\mathcal{A}^C} v$  in  $\mathcal{T}$  then
15      For  $x \in DS(t)$ , remove  $(v, x)$  from  $P(t)$ 
16       $DS(t) \leftarrow DS(t) - \{v\}$ 
17    else if  $v \prec_{\mathcal{A}^C} u$  in  $\mathcal{T}$  then
18      For  $x \in DS(t)$ , remove  $(u, x)$  from  $P(t)$ 
19       $DS(t) \leftarrow DS(t) - \{u\}$ 
  // Generating  $Q(t)$  from  $DS(t)$ 
20   $Q(t) \leftarrow \{(s, t) | s \in DS(t)\}$ 
21  for  $(s, t) \in Q(t)$  do
22    Ask  $(s, t)$  to crowds, and update  $\mathcal{T}$  with  $(s, t)$ 
23    if  $s \prec_{\mathcal{A}^C} t$  in  $\mathcal{T}$  then
24      break //  $t$  is a non-skyline tuple
25  if  $\forall s \in DS(t) : s \not\prec_{\mathcal{A}^C} t$  then
26     $\text{SKY}_{\mathcal{A}}(\mathcal{R}) \leftarrow \text{SKY}_{\mathcal{A}}(\mathcal{R}) \cup \{t\}$ 
27 return  $\text{SKY}_{\mathcal{A}}(\mathcal{R})$ 

```

checks tuples with the same values in \mathcal{A}^K , and prunes less preferred tuples in \mathcal{A}^C (lines 1-3). (2) It then builds dominating sets, and sorts them by $|DS(t)|$, incurring $O(n^2)$ in machine part (lines 6-7). (3) For each tuple $t \in \mathcal{R}$, $DS(t)$ is updated by $\text{SKY}_{\mathcal{A}^C}(DS(t))$ to remove non-skyline tuples (line 9). (4) It then generates all possible questions $P(t)$ to probe $DS(t)$ by $\text{freq}(u, v)$ (lines 10-11). By asking questions in $P(t)$, \mathcal{T} is updated. In addition $DS(t)$ and $P(t)$ are updated (lines 12-19). (5) After that, $Q(t)$ is generated from $DS(t)$ (lines 20-24). (6) Finally, if t is not dominated by any other tuples in $DS(t)$, t is appended to $\text{SKY}_{\mathcal{A}}(\mathcal{R})$ (lines 25-26).

THEOREM 1 (COMPLETENESS OF CROWDSKY) CrowdSky guarantees that all tuples in \mathcal{R} are complete.

PROOF We prove this by contradiction. Assume that t exists that is not determined as a complete tuple. This means a question (t, u) exists for t to be complete. Because the questions in CrowdSky are pruned by Corollaries 1 and 2, if (t, u) is not asked, a tuple v exists such that $v \prec_{\mathcal{A}^C} u$. In that case, (t, u) is unnecessary to check if t is complete, which is a contradiction. ■

As a result, if crowds always return correct answers, CrowdSky can identify all complete skyline tuples and the result is correct.

4. REDUCING LATENCY

In this section, we discuss how to reduce the number of rounds. Although existing work [25] addresses a parallelization method for

asking multiple questions, it is based on a different problem for entity resolution, thereby being inapplicable to our problem. We develop two parallelization methods that are suitable for computing a crowdsourced skyline. Specifically, we first propose a *partitioning method* using dominating sets (Section 4.1), and then improve it using *skyline layers* (Section 4.2).

4.1 Parallelization with Dominating Sets

Given two questions (s, t) and (u, v) , if asking (s, t) is not related to prune (u, v) and vice versa, it is said that they are *independent*. Meanwhile, if (s, t) can be pruned by asking (u, v) , (s, t) is said to be *dependent* on (u, v) . In order to remove unnecessary questions using our pruning methods in CrowdSky, the dependency of questions can happen as follows:

1. *Dominance relationship in \mathcal{A}^K (C1):* Given two tuples s and t such that $s \in DS(t)$, $Q(s)$ needs to be asked before generating $Q(t)$ by Corollary 1 (line 7 in CrowdSky). In other words, when s is determined as a non-skyline tuple, (s, t) is unnecessary in $Q(t)$.
2. *Overlap between $DS(s)$ and $DS(t)$ (C2):* We suppose that $DS(s)$ and $DS(t)$ share a common tuple u . When probing $DS(s)$ using the third pruning methods, u can be removed from $\text{SKY}_{\mathcal{A}^C}(DS(t))$ (line 9 in CrowdSky), and (u, t) can be unnecessary in $Q(t)$ by Corollary 2.
3. *Questions for $DS(t)$ (C3):* When $Q(t)$ is sequentially generated from $DS(t)$, t can be a non-skyline tuple (lines 20-24 in CrowdSky), and remaining questions in $Q(t)$ are no longer needed.

Based on these observations, our idea of parallelizing questions in CrowdSky is to identify independent questions as many as possible at each round. Specifically, we first develop a *partitioning method* using dominating sets. First, \mathcal{R} is partitioned into several subsets of tuples with the same sizes of dominating sets. Given $s, t \in \mathcal{R}$, if $|DS(s)| = |DS(t)|$, s and t cannot dominate each other (by Lemma 3). The questions for partitioned tuple sets can be asked together by avoiding dependent questions by (C1). We then check if dominating sets of tuples are disjoint. In that case, probing dominating sets can be parallelized without (C2). Lastly, because (C3) does not make parallelized questions, $Q(t)$ is sequentially generated from $DS(t)$.

EXAMPLE 7 (PARTITIONING METHOD) After the dominating sets are first computed, \mathcal{R} is partitioned into $\{\{a, g\}, \{d, k\}, \{c\}, \{f\}, \{h\}, \{j\}\}$ with the same sizes of dominating sets. For each partitioned set, it then checks if dominating sets are disjoint. Given $\{a, g\}$ and $\{d, k\}$, because $DS(a) \cap DS(g)$ and $DS(d) \cap DS(k)$ are disjoint as illustrated in Figure 4(a), the questions for $\{a, g\}$ and $\{d, k\}$ can be asked together. For $\{a, g\}$, $\{(a, b), (g, e)\}$ is asked in a round. For $\{d, k\}$, $\{(b, e), (i, l)\}$ (in $P(d)$ and $P(k)$) and $\{(d, e), (k, i)\}$ (in $Q(d)$ and $Q(k)$) are asked in 2 rounds. Because $\{c, f, h, j\}$ is partitioned separately, 6 questions are asked in 6 rounds. As a result, our partitioning method generates 12 questions during 9 rounds by saving 3 rounds. □

4.2 Parallelization with Skyline Layers

Although our partitioning method reduces the number of rounds, the degree of parallelization is rather limited by keeping all dependencies of questions. To alleviate this problem, we adopt *skyline layers* that effectively visualize the dominance relationships between tuples in \mathcal{A}^K . Figure 5 depicts skyline layers for the toy dataset in Figure 1(a). To build skyline layers, skylines are

Figure 5: Skyline layers for the toy dataset in Figure 1(a)

computed in an iterative manner. Initially, SL_1 is computed by $\text{SKY}_{\mathcal{A}^K}(\mathcal{R})$. Then, the i -th layer is computed by $\text{SKY}_{\mathcal{A}^K}(\mathcal{R} - \bigcup_{j=1}^{i-1} SL_j)$ in an iterative manner.

DEFINITION 6 (SKYLINE LAYER) The i -th skyline layer SL_i is a set of skyline tuples in $\mathcal{R} - \bigcup_{j=1}^{i-1} SL_j$, i.e., $SL_i = \{t \in \mathcal{R} - \bigcup_{j=1}^{i-1} SL_j \mid \forall s \in \mathcal{R} - \bigcup_{j=1}^{i-1} SL_j : s \not\prec_{\mathcal{A}^K} t\}$.

After building all layers, the dominance relationship of tuples in \mathcal{A}^K is constructed. Similar to a *dominating graph* [27], the dominance relationship can be represented by a directed edge between two tuples across different layers. In particular, our skyline layers permit the dominance relationship between tuples in any two layers, e.g., $e \rightarrow c$ and $i \rightarrow h$ in Figure 5. Note that the dominance relationship via transitivity can be inferred from multiple edges.

We now explain how to make use of skyline layers to reduce the number of rounds. Let $c(t)$ denote a set of tuples that directly point to t , i.e., $c(t) = \{s \in \mathcal{R} \mid s \rightarrow t\}$. For each tuple $t \in \mathcal{R}$, we check if all tuples in $c(t)$ are complete. If so, the questions for t are asked *independently* of those of other tuples. When all tuples in $c(t)$ are determined as complete tuples, it implies that all tuples in $DS(t)$ are also complete. Because this method can effectively check the dominance relationships of tuples in (C1), we can significantly improve the magnitude of parallelization. Meanwhile, it is observed that (C2) is a main bottleneck for parallelizing questions. We thus violate the dependency of questions in (C2), by generating additional questions for (C2). (Our empirical study shows that the number of additional questions is negligible.)

Algorithm 2 describes the procedure of parallelizing questions using skyline layers. Let \mathcal{C} be a set of complete tuples in \mathcal{R} . (1) \mathcal{C} is initialized as SL_1 (line 4). (2) For each tuple $t \in \mathcal{R}$, if all tuples in $c(t)$ are complete, the questions for t are asked in parallel. (lines 5-7). (3) After asking questions for t , $\text{SKY}_{\mathcal{A}^K}(\mathcal{R})$ and \mathcal{C} are updated (lines 8-10). This process continues until every tuple in \mathcal{R} has been determined as a complete tuple. Because this method is based on the same pruning methods used in **CrowdSky**, our proposed parallelization methods can assure the correctness of crowd-enabled skyline computation.

EXAMPLE 8 (PARALLELIZATION WITH SKYLINE LAYERS) Given the skyline layers in Figure 5, Table 3 depicts the procedure of parallelization using skyline layers. First, \mathcal{C} is initialized as SL_1 , i.e., $\mathcal{C} = \{b, e, i, l\}$. Because $c(a) = \{b\}$, $c(g) = \{e\}$, $c(d) = \{b, e\}$ and $c(k) = \{i, l\}$ are all complete tuples, $\{(a, b), (g, e), (b, e), (i, l)\}$ is asked in parallel (round 1), and $\mathcal{C} = \{b, e, i, l, a, g\}$ is updated (underlines in Table 3). After that, because $c(c) = \{a, e\}$ is complete, $\{(d, e), (k, i)\}$ is asked with $\{(c, e)\}$, and $\mathcal{C} = \{b, e, i, l, a, g, d, k, c\}$ is updated (round 2). Because $c(f) = \{a, d\}$ and $c(h) = \{d, g, i\}$ are complete, the questions for f and h are asked (rounds 3-4), and $\mathcal{C} = \{b, e, i, l, a, g, d, k, c, f, h\}$ is updated. Lastly, when $c(j) = \{f, h\}$ is complete, the questions for

Table 3: Procedure of asking questions using skyline layers in Figure 4(a)

t	$c(t)$	1	2	3	4	5	6
a	$\{b\}$	(a, b)					
g	$\{e\}$	(g, e)					
d	$\{b, e\}$	(b, e)	(d, e)				
k	$\{i, l\}$	(i, l)	(k, i)				
c	$\{a, e\}$	(c, e)					
f	$\{a, d\}$			(f, e)			
h	$\{d, g, i\}$			(e, i)	(h, e)		
j	$\{f, h\}$					(f, h)	(j, f)

j are asked (rounds 5-6). As a result, our parallelization method generates 12 questions during 6 rounds. \square

5. IMPROVING ACCURACY OF ANSWERS

Because the answers of crowds are often erroneous, how to improve the accuracy is a central issue in crowdsourcing. As discussed in [24, 25], it was treated as a research problem orthogonal to the problem of minimizing the number of questions. Existing work [6, 11, 18] developed how to improve the accuracy for each question using *query-independent* methods.

As the simplest method, *majority voting* is used by assigning multiple workers per question. Let ω denote the number of workers per question, and p denote the probability that each worker's answer is correct. The probability that question (u, v) is correct can be modeled as the binomial distribution.

$$P(u, v) = \sum_{i=\lceil \frac{\omega}{2} \rceil}^{\omega} \binom{\omega}{i} p^i (1-p)^{\omega-i},$$

where ω is an odd integer. This method can improve the accuracy per question, but does not consider the *importance* of questions in computing a skyline. This method is called *static voting*. (In our experiments, $\omega = 5$ by default.)

As the *query-dependent* method, we develop a heuristic method to reflect the importance of questions. When computing the skyline, it is observed that the questions with many dominance relationships in \mathcal{A}^K are more influential in identifying a more accurate preference tree \mathcal{T} in \mathcal{A}^C . Based on this observation, we propose to use the *frequency* of questions $\text{freq}(u, v)$ for quantifying the importance of (u, v) , i.e., $\text{freq}(u, v) = |\{x \in \mathcal{R} \mid u \prec_{\mathcal{A}^K} x \wedge v \prec_{\mathcal{A}^K} x\}|$. That is, as $\text{freq}(u, v)$ gets larger, (u, v) becomes more important. Given question (u, v) , the different numbers of workers can be assigned, depending on $\text{freq}(u, v)$. We refer to this method as *dynamic voting*. Note that the dynamic voting can help prevent the propagation of false dominance relationships.

Table 4: Parameter settings over synthetic datasets

parameters	value	default
cardinality n	2K, 4K, 6K, 8K, 10K	4K
# of known attributes $ \mathcal{A}^K $	2, 3, 4, 5	4
# of crowd attributes $ \mathcal{A}^C $	1, 2, 3	1
data distribution	IND, ANT	

For instance, based on the idea of the dynamic voting, one may dynamically assign the number of workers using two parameters α and β ($\alpha < \beta$ and $\alpha, \beta \geq 0$) as follows. Given $\text{freq}(u, v)$, we choose the number of workers ω' with the following inequalities.

$$\omega' = \begin{cases} \omega - 2, & \text{if } \text{freq}(u, v) < \alpha \\ \omega, & \text{if } \alpha \leq \text{freq}(u, v) < \beta \\ \omega + 2, & \text{if } \text{freq}(u, v) \geq \beta \end{cases}$$

By considering the importance of questions, our dynamic voting can improve the accuracy of the skyline result compared to the static voting. Note that it can be easily extended for multiple categories with three or more cases.

6. EXPERIMENTS

In this section, we first evaluate our proposed algorithm over synthetic datasets with extensive parameter settings (Section 6.1). We show the performance of our proposed algorithm in terms of three key factors. We then evaluate our algorithm using the Amazon Mechanical Turk over real-life datasets (Section 6.2).

6.1 Evaluation in Synthetic Datasets

We first evaluate our proposed algorithm over synthetic datasets. Because real-life datasets are limited for evaluating extensive settings, we adopted benchmark datasets [2] that are widely used in skyline evaluation. In particular, we used two data distributions, *independent* (IND) and *anti-correlated* (ANT) in [2]. All attribute values were randomly generated from real values in $[0, 1]$. The values on crowd attributes were only used for obtaining the answers of crowds for simulated questions. Table 4 summarizes parameter settings over synthetic datasets.

We validate our proposed algorithm for three key factors: monetary cost, latency, and accuracy (as discussed in Section 2.1). Because the running time in crowdsourcing part is much slower than generating questions in machine part, we focus on evaluating the number of rounds for latency. All experiments were conducted in Windows 7 running on Intel Core i7 950 3.07 GHz CPU with 16GB RAM. All the algorithms were implemented in C++. The average values of 10 runs are reported for all experiments.

Monetary cost. When the fixed amount of a reward per question is paid, the monetary cost is proportional to the number of questions asked to crowds. We thus use the number of questions to measure the monetary cost. As one of the sorting algorithms, *tournament sort* is used as a baseline, denoted by **Baseline**. When the number of rounds is not limited, tournament sort can produce the *total order* of tuples with the minimum number of questions. An existing work [12] studied crowd-enabled skyline queries, but focused on selecting the most influential unary questions for a restricted budget. Because the optimization methods in [12] are not effective for reducing questions in our problem setting, the direct comparison between CrowdSky and [12] is not fair to [12]. As such, we simulate the unary questions in [12] for comparing the accuracy, and mainly focus on scrutinizing CrowdSky to quantify the advantage of optimization methods. Specifically, it is divided into four

phases: DSet (Section 3.1), P1 (Section 3.2), P2 (Section 3.3), and P3 (Section 3.4).

Figures 6(a) and 7(a) depict the number of questions over varying cardinality. Note that DSet is basically used for all pruning methods. It is clear that P1+P2+P3 minimizes the number of questions over all parameter settings, *e.g.*, reducing the number of questions 10 times more than that of **Baseline** over independent distribution. In particular, several interesting observations are found in Figures 6(a) and 7(a): (1) While DSet produces fewer questions than **Baseline** in independent distribution, it is reversed in anti-correlated distribution. This is because the number of skyline tuples increases exponentially with the cardinality over anti-correlated distribution. (2) Both P1 and P2 can contribute to reducing unnecessary questions. Notably, P2 (using the transitivity of tuples in \mathcal{A}^C) is fairly effective over anti-correlated distribution. (3) As expected, P3 (probing dominating sets) reduces a more number of unnecessary questions over anti-correlated distribution.

Figures 6(b) and 7(b) report the number of questions over varying $|\mathcal{A}^K|$. While **Baseline** shows a constant performance regardless of $|\mathcal{A}^K|$, our pruning methods reduce the number of questions as $|\mathcal{A}^K|$ increases. This is because the size of dominating sets tends to decrease with $|\mathcal{A}^K|$. We also found two key observations: (1) P1+P2+P3 minimizes the number of questions over all parameter settings. (2) When $|\mathcal{A}^K|$ is low, our pruning methods significantly reduce unnecessary questions, and are much more effective over anti-correlated distribution than independent distribution. When $|\mathcal{A}^K| = 2$, P1+P2+P3 reduces the number of questions in DSet by two orders of magnitude.

Figures 6(c) and 7(c) report the number of questions over varying $|\mathcal{A}^C|$. When $|\mathcal{A}^C| > 1$, suppose that all methods simply generate $|\mathcal{A}^C|$ questions in \mathcal{A}^C . (It is possible to use a round-robin strategy for multiple crowd attributes to reduce unnecessary questions as they become incomparable in \mathcal{A}^C , but it is not applied to our evaluation.) (1) As $|\mathcal{A}^C|$ increases, the number of questions increases for all methods. (2) Interestingly, when $|\mathcal{A}^C| = 2$, P3 becomes marginal. As \mathcal{A}^C increases, P3 becomes less effective for generating dominance relationships in \mathcal{A}^C . This implies that probing dominating sets mainly incurs the questions for tuples with incomparable relationships. In high dimensionality in \mathcal{A}^C , we have to consider to use P3 in CrowdSky.

Latency. In order to measure latency, we used the number of rounds in performing an algorithm. We compared the following four algorithms: (1) **Baseline** is tournament sort; (2) **Serial** asks a single question in a round; (3) **ParallelDSet** is our parallelization algorithm using dominating sets (Section 4.1); (4) **ParallelSL** is our parallelization algorithm using skyline layers (Section 4.2).

Figure 8 reports the number of rounds over varying cardinality. Note that the y-axis is log-scaled. The gap between **Serial** and **ParallelDSet** widens by one order of magnitude as cardinality increases. In addition, **ParallelSL** outperforms **ParallelDSet** by two orders of magnitude, *e.g.*, **ParallelSL** only needs about 20-30 rounds in both distributions. Although we did not report the number of questions for parallelization, it is found that **ParallelDSet** generates the same number of questions for **Serial**, and **ParallelSL** generates approximately 10% more questions than **ParallelDSet**, by violating the dependency of questions in (C2).

Figure 9 reports the number of rounds over varying dimensionality $|\mathcal{A}^K|$. Interestingly, while **Serial** incurs more rounds with higher $|\mathcal{A}^K|$, **ParallelDSet** and **ParallelSL** decrease the number of rounds with $|\mathcal{A}^K|$. This implies that the degree of parallelization becomes higher as $|\mathcal{A}^K|$ increases. As consistently observed in Figure 8, **ParallelSL** significantly outperforms **ParallelDSet** by two orders of magnitude in both distributions.

Figure 6: Comparisons on the number of questions over independent distribution

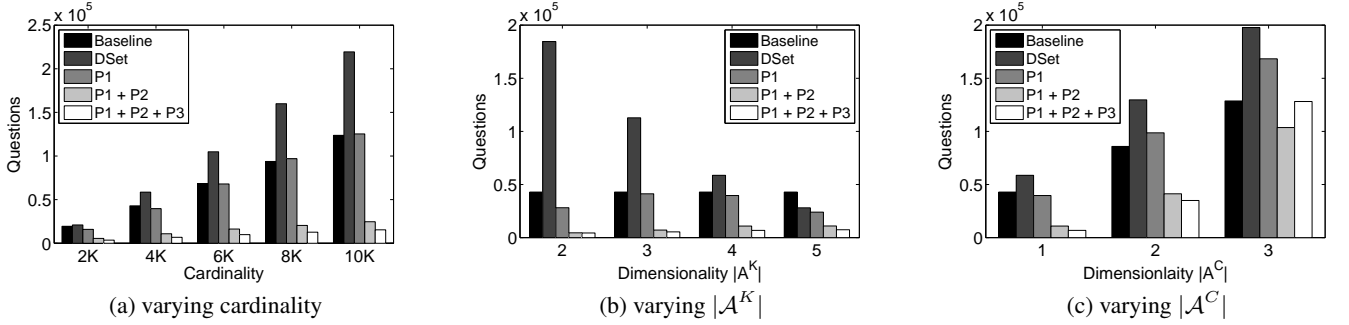

Figure 7: Comparisons on the number of questions over anti-correlated distribution

Figure 8: Comparisons on the number of rounds over varying cardinality

Figure 9: Comparisons on the number of rounds over varying dimensionality of known attributes

Accuracy. The crowdsourced skyline is defined as $\text{SKY}_{\mathcal{A}}(\mathcal{R})$. To measure the accuracy of skyline results, we only use a set of newly retrieved skyline tuples by crowdsourcing, *i.e.*, $\text{SKY}_{\mathcal{A}}(\mathcal{R}) - \text{SKY}_{\mathcal{A}^K}(\mathcal{R})$, with two metrics, *precision* and *recall*, which are widely used in Information Retrieval.

We first compared two assignment methods, *StaticVoting* and *DynamicVoting* in *CrowdSky* (as in Section 5). By default, we set $\omega = 5$ and $p = 0.8$. While *StaticVoting* equally assigns ω per question, *DynamicVoting* assigns $\omega + 2$, ω , $\omega - 2$ depending on the frequency of questions. For fair comparisons, we assigned the same total number of workers in both methods. The assignment of the number of workers in *DynamicVoting* is tuned as: the initial 30% questions are assigned to $\omega + 2$, and the last 30% questions are assigned to $\omega - 2$. This implies that the initial questions in *DynamicVoting* are more important than other questions.

Figure 10 reports the accuracy of two voting methods over varying cardinality. It is clear that *DynamicVoting* shows higher accuracy than *StaticVoting* for both metrics. Note that *DynamicVoting* improves the overall accuracy by assigning more workers to more

important questions and by reducing the propagation for false positives/negatives. In addition, the precision is higher than the recall in all parameter settings. While most of the skyline tuples are decided correctly, some correct skyline tuples are determined as non-skyline tuples. This is because our methods focus on asking questions for skyline candidates and do not perform an additional validation for non-skyline tuples.

We also compared the following three algorithms: (1) *Baseline* generates the total order of tuples in \mathcal{A}^K by performing the tournament sort, (2) *Unary* generates the total order of tuples by asking unary questions (as done in [12]), and (3) *CrowdSky* adopts *DynamicVoting*. To simulate the unary questions in [12], we randomly select a value from the normal distribution of actual value in \mathcal{A}^C . In this setting, it is found that *Unary* is more accurate for obtaining the total order of tuples than *Baseline*, *i.e.*, it is more favorable for *Unary*.

Figure 11 reports the accuracy of comparing *CrowdSky* and the two existing methods. Interestingly, even though *Baseline* generates more numbers of questions than *CrowdSky*, *Baseline* is

Figure 10: Accuracy comparisons of two voting methods in CrowdSky over independent distribution

Figure 11: Accuracy comparisons of CrowdSky with existing methods (i.e., Unary as in [12]) over independent distribution

worse than CrowdSky. Because more questions in Baseline incur wrong answers, the total order of tuples in Baseline is less effective for identifying a correct skyline. In contrast, CrowdSky generates questions more selectively for skyline candidates. While Unary is better than Baseline, it is worse than CrowdSky. Because the pruning methods in [12] do not work well in our problem setting, Unary is less effective for identifying correct skyline tuples.

6.2 Evaluation in Real-life Datasets

We used three real-life datasets to validate our proposed algorithms: (1) **Rectangles**, adopted from [14], contains 50 images whose sizes are $\{(30 + 3i) \times (40 + 5i) | i \in [0, 50)\}$ and are randomly rotated. (2) **IMDb Movies** includes 50 popular movies released in 2000-2012 (<http://www.imdb.com/>). (3) **MLB players** includes 40 baseball pitchers played in 2013 (<http://espn.go.com/mlb/stats/>). For these datasets, we used small-scale datasets in order to manage the monetary cost in real-life experiments, and executed the following crowd-enabled skyline queries:

Q1: Find the skyline using rectangle data with $\mathcal{A}^K = \{\text{width}, \text{height}\}$ and $\mathcal{A}^C = \{\text{area}\}$. The larger values in \mathcal{A}^K and \mathcal{A}^C are more preferred. As the ground truth for crowd attribute area can be obtained using width and height, the accuracy of the crowdsourced skyline can be measured.

Q2: Find the skyline using movie data with $\mathcal{A}^K = \{\text{box_office}, \text{release_year}\}$ and $\mathcal{A}^C = \{\text{rating}\}$. The larger values in \mathcal{A}^K and \mathcal{A}^C are more preferred. Since IMDb shows aggregated rating scores of movies, we compare the crowdsourced skyline (using preferences culled from crowds) against the IMDb rating-based skyline.

Q3: Find the skyline using MLB player data with $\mathcal{A}^K = \{\text{wins}, \text{strikes_outs}, \text{ERA}\}$ and $\mathcal{A}^C = \{\text{valuable}\}$. The larger values are more preferred, except for ERA. The crowd attribute

Figure 12: Comparisons of three queries over real-life datasets

valuable is the preference of crowds on how *valuable* each pitcher is. For this query, we indirectly compare the crowdsourced skyline against the candidates of the “Cy Young” award, given to the best pitchers annually.

The Amazon Mechanical Turk (AMT), a well-known crowdsourcing platform, was used for asking questions to crowds in real-life datasets. The budget per question was set to \$0.02, and 5 workers were assigned for each question, i.e., $\omega = 5$. Let r denote the total number of rounds, and $|Q_i|$ denote the number of questions at the i -th round. The total monetary cost is thus calculated as: $0.02 \times 5 \times \sum_{i=1}^r \lceil \frac{|Q_i|}{5} \rceil$, where 5 questions are issued at each task. To filter out spam workers, we only permitted *Masters* workers who are qualified as the most reliable workers in AMT.

Monetary cost. Figure 12(a) compares the monetary cost between Baseline and CrowdSky. Note that CrowdSky saves the cost of Baseline by 3-4 times. (Because the cardinality of real-life datasets is smaller than that of synthetic datasets, the performance gap between Baseline and CrowdSky is reduced.) For $Q1$ and $Q2$, while Baseline needs more than 200 questions, CrowdSky generates about 50 questions, where most questions are used for validating non-skyline tuples.

Latency. Figure 12(b) compares the latency of three algorithms: Baseline, ParallelIDSet, and ParallelISL. For $Q1$, $Q2$, and $Q3$, the average working time per HIT was 22 secs, 49 secs, and 1 min 33 secs, respectively, implying that $Q3$ is the most difficult task. While Baseline incurs more than 140 rounds over all queries, ParallelIDSet and ParallelISL only generate less than 30 rounds. In addition, ParallelISL generates 50% less rounds than ParallelIDSet, without increasing the cost for all queries. For $Q3$, while Baseline and ParallelIDSet need 140 and 19 rounds, ParallelISL computes the skyline with only 6 rounds.

Accuracy. For $Q1$, CrowdSky identifies the same skyline as the ground truth, yielding *Precision* = 1.0 and *Recall* = 1.0. For $Q2$, the crowdsourced skyline includes 5 movies such as {Avatar, The Avengers, Inception, The Lord of Rings: The Fellowship of the Ring, The Dark Knight Rises}. Except for the existing skyline {Avatar, The Avengers} in \mathcal{A}^K , we found that the average rating of three skyline movies is very high (i.e., 8.7 out of 10.0) in IMDb, indicating that crowds were able to find decent skyline movies. For $Q3$, the skyline includes four players such as {Clayton Kershaw, Bartolo Colon, Yu Darvish, Max Scherzer} who were Cy Young award candidates, representing the best pitchers, in 2013. In particular, “Clayton Kershaw” and “Max Scherzer” were the winners of the Cy Young award in 2013. As such, we claim that the crowdsourced skyline be reasonably accurate. Based on the results, we argue that CrowdSky yields high accuracy while keeping the monetary cost and the latency low.

7. RELATED WORK

Skyline queries have been actively studied for assisting multi-criteria decision making applications. Pioneered by [2], skyline queries are used for various data settings such as distributed and stream environments. Tuples are represented by incomplete and probabilistic values, and data types vary from partially-ordered and categorical attributes. Existing work focused on developing efficient skyline computation with pre-defined preferences. In contrast, we aimed to collect missing preferences from crowds.

In recent years, in data management community, there have been active investigations toward crowd-enabled algorithms. Some of recent highlights include the following data operations with crowdsourcing embedded: selection [6, 18, 21], max [8, 22, 23], sorting [14], top- k [4], top- k set [20], join [14, 24, 25, 26], and group by [4]. Based on these advancements, our work combines the skyline queries with crowdsourcing.

In particular, our crowd-enabled skyline query is related to [12], which is the first work to address the problem of skyline queries with a crowdsourcing idea. However, our work has clear differences from [12] as follows:

- *Problem formulation:* While [12] used crowds to improve the accuracy of incomplete skyline queries, our work addressed a complete skyline by collecting all missing preferences in crowd attributes.
- *Optimization direction:* While [12] mainly aimed at maximizing the accuracy of skyline results, we considered three factors (monetary cost, latency, and accuracy) together.
- *Formats of questions:* Since [12] used the quantitative questions, it is inapplicable for crowd attributes with a large range. On the contrary, since our work is based on the qualitative questions, it is easier for crowds to evaluate tuples in crowd attributes without any constraints.

Because the optimization methods in [12] are not effective for reducing questions in our problem setting, the direct comparison between CrowdSky and [12] would have been unfair to [12]. As such, in Section 6, we have simulated the unary questions in [12] for comparing the accuracy in our setting, and indirectly demonstrated the superiority of CrowdSky with a strong evidence (*i.e.*, Figure 11).

8. CONCLUSIONS

In this paper, we have studied the problem of computing skyline queries with crowdsourcing. Specifically, we dealt with three key factors such as monetary cost, latency, and accuracy. Our proposed algorithm first aimed to minimize the number of questions with several pruning methods on top of the notion of a dominating set. We then developed an algorithm to minimize the number of rounds using skyline layers. We lastly improved the accuracy of a crowdsourced skyline using dynamic majority voting. Our experimental results showed that our proposed algorithm optimizes the three key factors effectively over synthetic and real-life datasets.

ABSTRACT

Keyword search is the most popular querying technique on semistructured data. Keyword queries are simple and convenient. However, as a consequence of their imprecision, there is usually a huge number of candidate results of which only very few match the user's intent. Unfortunately, the existing semantics for keyword queries are ad-hoc and they generally fail to "guess" the user intent. Therefore, the quality of their answers is poor and the existing algorithms do not scale satisfactorily.

In this paper, we introduce the novel concept of cohesive keyword queries for tree data. Intuitively, a cohesiveness relationship on keywords indicates that they should form a cohesive whole in a query result. Cohesive keyword queries allow term nesting and keyword repetition. Cohesive keyword queries bridge the gap between flat keyword queries and structured queries. Although more expressive, they are as simple as flat keyword queries and not require any schema knowledge. We provide formal semantics for cohesive keyword queries and rank query results on the proximity of the keyword instances. We design a stack based algorithm which efficiently evaluates cohesive keyword queries. Our experiments demonstrate that our approach outperforms in quality previous filtering semantics and our algorithm scales smoothly on queries of even 20 keywords on large datasets.

1. INTRODUCTION

Keyword search has been by far the most popular technique for retrieving data on the web. The success of keyword search relies on two facts: First, the user does not need to master a complex structured query language (e.g., SQL, XQuery, SPARQL). This is particularly important since the vast majority of people who retrieve information from the web do not have expertise in databases. Second, the user does not need to have knowledge of the schema of the data sources over which the query is evaluated. In practice, in the

web, the user might not even be aware of the data sources which contribute results to her query. The same keyword query can be used to extract data from multiple data sources which have different schemas and they possibly adopt different data models (e.g., relational, tree, graph, flat documents).

There is a price to pay for the simplicity, convenience and flexibility of keyword search. Keyword queries are imprecise in specifying the query answer. They lack expressive power compared to structured query languages. As a consequence, there is usually a very large number of candidate results from which very few are relevant to the user intent. This weakness incurs at least two major problems: (a) because of the large number of candidate results, previous algorithms for keyword search are of high complexity and they cannot scale satisfactorily when the number of keywords and the size of the input dataset increase, and (b) correctly identifying the relevant results among the plethora of candidate results, becomes a very difficult task. Indeed, it is practically impossible for a search system to "guess" the user intent from a keyword query and the structure of the data source.

The focus of this work is on keyword search over web data which are represented as trees. Currently, huge amounts of data are exported and exchanged in tree-structure form [31, 33]. Trees can conveniently represent data that are semistructured, incomplete and irregular as is usually the case with data on the web. Multiple approaches assign semantics to keyword queries on data trees by exploiting structural and semantic features of the data in order to automatically filter out irrelevant results. Examples include Smallest LCA [18, 40, 37, 10], Exclusive LCA [16, 41, 42], Valuable LCA [11, 20], Meaningful LCA [24, 38], MaxMatch [28], Compact Valuable LCA [20] and Schema level SLCA [15]. A survey of some of these approaches can be found in [29]. Although filtering approaches are intuitively reasonable, they are sufficiently ad-hoc and they are frequently violated in practice resulting in low precision and/or recall. A better technique is adopted by other approaches which rank the candidate results in descending order of their estimated relevance. Given that users are typically interested in a small number of query results, some of these approaches combine ranking with top-k algorithms for keyword search. The ranking is performed using a scoring function and is usually based on IR-style metrics for flat documents (e.g., $tf \cdot idf$ or PageRank) adapted to the tree-structure form of the data [16, 11, 3, 5, 21, 10, 38, 23, 29, 32]. Nevertheless,

scoring functions, keyword occurrence statistics and probabilistic models alone cannot capture effectively the intent of the user. As a consequence, the produced rankings are, in general, of low quality [38].

Our approach. In this paper, we introduce a novel approach which allows the user to specify cohesiveness relationships among keywords in a query, an option not offered by the current keyword query languages. Cohesiveness relationships group together keywords in a query to define indivisible (cohesive) collections of keywords. They partially relieve the system from guessing without affecting the user who can naturally and effortlessly specify such relationships.

For example, consider the keyword query `{XML John Smith George Brown}` to be issued against a large bibliographic database. The user is looking for publications on XML related to the authors John Smith and George Brown. If the user can express the fact that the instances of John and Smith should form a unit where the instances of the other keywords of the query George, Brown and XML cannot slip into to separate them (that is, the instances of John and Smith form a *cohesive whole*), the system would be able to return more accurate results. For example, it will be able to filter out publications on XML by John Brown and George Smith. It will also filter out a publication which cites a paper authored by John Davis, a report authored by George Brown and a book on XML authored by Tom Smith. This information is irrelevant and no one of the previous filtering approaches (e.g., ELCA, VLCA, CVLCA, SLCA, MLCA, MaxMach etc.) is able to automatically exclude it from the answer of the query. Furthermore, specifying cohesiveness relationships prevents wasting time searching for these irrelevant results. We specify cohesiveness relationships among keywords by enclosing them between parentheses. For example, the previous keyword query would be expressed as `(XML (John Smith) (George Brown))`.

Note that the importance of bridging the gap between flat keyword queries and structured queries in order to improve the accuracy (and possibly the performance) of keyword search has been recognized before for flat text documents. Google allows a user to specify, between quotes, a phrase which has to be matched intact against the text document. However, specifying a cohesiveness relationship on a set of keywords is different than phrase matching over flat text documents in IR. Indeed, a cohesiveness relationship on a number of keywords over a data tree does not impose any syntactic restriction (e.g., the order of the keywords) on the instances of these keywords on the data tree. It only requires that the instances of these keywords form a cohesive unit. We provide formal semantics for queries with cohesiveness relationships on tree data in Section 2.

Cohesiveness relationships can be nested. For instance the query `(XML (John Smith) (citation (George Brown)))` looks for a paper on XML by John Smith which cites a paper by George Brown. The cohesive keyword query language conveniently allows also for keyword repetition. For instance, the query `(XML (John Smith) (citation (John Brown)))` looks for a paper on XML by John Smith which cites a paper by John Brown.

Cohesive queries better express the user intent while being as simple as flat keyword queries. However, despite their increased expressive power, they enjoy both advantages of traditional keyword search: they do not require any previous knowledge of a query language or of the schema of the data

sources. The users can naturally and effortlessly specify cohesiveness relationships when writing a query. The benefits, though, in query answer quality and performance compared to other flat keyword search approaches are impressive.

Contribution. The main contributions of our paper are as follows:

- We formally introduce a novel keyword query language which allows for cohesiveness relationships, cohesiveness relationship nesting and keyword repetition. Our semantics interpret the subtrees rooted at the LCA of the instances of cohesively related keywords in the data tree as impenetrable units where the instances of the other keywords cannot slip in.
- We rank the results of cohesive keyword queries on tree data based on the concept of LCA size. The LCA size reflects the proximity of keywords in the data tree and, similarly to keyword proximity in IR, it is used to determine the relevance of the query results.
- We design an efficient multi-stack-based algorithm which exploits a lattice of stacks—each stack corresponding to a different partition of the query keywords. Our algorithm does not rely on auxiliary index structures and, therefore, can be exploited on datasets which have not been preprocessed.
- We show how cohesive relationships can be leveraged to lower the dimensionality of the lattice and dramatically reduce its size and improve the performance of the algorithm.
- We analyze our algorithm and show that for a constant number of keywords it is linear on the size of the input keywords' inverted lists, i.e., to the dataset size. Our analysis further shows that the performance of our algorithm essentially depends on the maximum cardinality of the largest cohesive term in the keyword query.
- We run extensive experiments on different real and benchmark datasets to assess the effectiveness of our approach and the efficiency and scalability of our algorithm. Our results show that our approach largely outperforms previous filtering approaches, which do not benefit from cohesiveness relationships, achieving in most cases perfect precision and recall. They also show that our algorithm scales smoothly when the number of keywords and the size of the dataset increase achieving interactive response times even with queries of 20 keywords having in total several thousands of instances on large datasets.

2. DATA AND QUERY MODEL

We consider data modeled as an ordered labeled tree. Every node has an id, a label and possibly a value. For identifying tree nodes we adopt the Dewey encoding scheme [9], which encodes tree nodes according to a preorder traversal of the data tree. The Dewey encoding scheme naturally expresses ancestor-descendant and parent-child relationships among tree nodes and conveniently supports the processing of nodes in stacks [16].

A keyword k may appear in the label or in the value of a node n in the data tree one or multiple times, in which case we say that node n constitutes an *instance* of k . A node may contain multiple distinct keywords in its value and label, in which case it is an instance of multiple keywords.

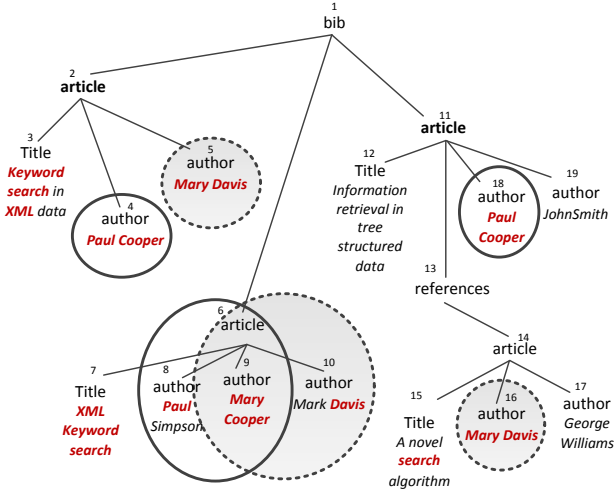

Figure 1: Example data tree D_1

2.1 Cohesive semantics

A *cohesive keyword query* is a keyword query, which besides keywords may also contain groups of keywords called terms. Intuitively, a term expresses a cohesiveness relationship on keywords and/or terms. More formally, a cohesive keyword query is recursively defined as follows:

DEFINITION 1 (COHESIVE KEYWORD QUERY). A term is a multiset of at least two keywords and/or terms. A cohesive keyword query is: (a) a set of a single keyword, or (b) a term. Sets and multisets are delimited within a query using parentheses.

For instance, the expression $((\text{title XML})((\text{John Smith}) \text{author}))$ is a keyword query. Some of its terms are $T_1 = (\text{title XML})$, $T_2 = ((\text{John Smith}) \text{author})$, $T_3 = (\text{John Smith})$, and T_3 is nested into T_2 .

A keyword may occur multiple times in a query. For example, in the keyword query $((\text{journal (Information Systems)} ((\text{Information Retrieval}) \text{Smith})))$ the keyword **Information** occurs twice, once in the term **(Information Systems)** and once in the term **(Information Retrieval)**.

In the rest of the paper, we may refer to a cohesive keyword query simply as query. The syntax of a query Q is defined by the following grammar where the non-terminal symbol T denotes a term, and the terminal symbol k denotes a keyword:

$$\begin{aligned} Q &\rightarrow (k) \mid T \\ T &\rightarrow (S \ S) \\ S &\rightarrow S \ S \mid T \mid k \end{aligned}$$

We now move to define the semantics of cohesive keyword queries. Keyword queries are embedded into data trees. In order to define query answers, we need to introduce the concept of query embedding. In cohesive keyword queries, m occurrences of the same keyword in a query are embedded to one or multiple instances of this keyword as long as these instances collectively contain at least m times this keyword. Cohesive keyword queries may also contain terms, which, as mentioned before, express a cohesiveness relationship on their keyword occurrences. In tree structured data, the keyword instances in the data tree (which are nodes) are represented by their LCA [36, 16, 29]. The instances of the

keywords of a term in the data tree should form a cohesive unit. That is, the subtree rooted at the LCA of the instances of the keywords which are internal to the term should be impenetrable by the instances of the keywords which are external to the term. Therefore, if l is the LCA of a set of instances of the keywords in a term T , i is one of these instances and i' is an instance of a keyword not in T , then $\text{lca}(i', i) = \text{lca}(i', l) \neq l$.

As an example, consider query $Q_1 = (\text{XML keyword search (Paul Cooper)} (\text{Mary Davis}))$ issued against the data tree D_1 of Figure 1. In Figure 1, keyword instances are shown in bold and the instances of the keywords of a term below the same article are encircled. The mapping that assigns Paul to node 8, Mary and Cooper to node 9 and Davis to node 10 is not an embedding of Q_1 since Mary slips into the encircled subtree of Paul and Cooper rooted at article node 6: the two circles of article node 6 overlap. These ideas are formalized below.

DEFINITION 2 (QUERY EMBEDDING). Let Q be a keyword query on a data tree D . An embedding of Q to D is a function e from every keyword occurrence in Q to an instance of this keyword in D such that:

- if k_1, \dots, k_m are distinct occurrences of the same keyword k in Q and $e(k_1) = \dots = e(k_m) = n$, then node n contains keyword k at least m times.
- if k_1, \dots, k_n are the keyword occurrences of a term T , k is a keyword occurrence not in T , and $l = \text{lca}(e(k_1), \dots, e(k_n))$ then: (i) $e(k_1) = \dots = e(k_n)$, or (ii) $\text{lca}(e(k), l) \neq l$.

Given an embedding e of a query Q involving the keyword occurrences k_1, \dots, k_m on a data tree D , the *minimum connecting tree* (MCT) M of e on D is the minimum subtree of D that contains the nodes $e(k_1), \dots, e(k_m)$. Tree M is also called an MCT of query Q on D . The root of M is the *lowest common ancestor* (LCA) of $e(k_1), \dots, e(k_m)$ and defines one result of Q on D . For instance, one can see that the article nodes 2 and 11 are results of the example query Q_1 on the example tree D_1 . In contrast, the article node 6 is not a result of Q_1 .

We use the concept of LCA size to rank the results in a query answer. Similarly to metrics for flat documents in information retrieval, LCA size reflects the proximity of keyword instances in the data tree. The *size* of an MCT is the number of its edges. Multiple MCTs of Q on D with different sizes might be rooted at the same LCA node l . The size of l (denoted $\text{size}(l)$) is the minimum size of the MCTs rooted at l .

For instance, the size of the result article node 2 of query Q_1 on the data tree D_1 is 3 while that of the result article node 11 is 6 (note that there are multiple MCTs of different sizes rooted at node 11 in D_1).

DEFINITION 3. The answer to a cohesive keyword query Q on a data tree D is a list $[l_1, \dots, l_n]$ of the LCAs of Q on D such that $\text{size}(l_i) \leq \text{size}(l_j)$, $i < j$.

For example, article node 2 is ranked above article node 11 in the answer of Q_1 on D_1 .

2.2 Result ranking using cohesive terms

The LCA size naturally reflects the overall proximity of the query keyword instances in the subtree of a result LCA. Every result LCA contains partial LCAs corresponding to

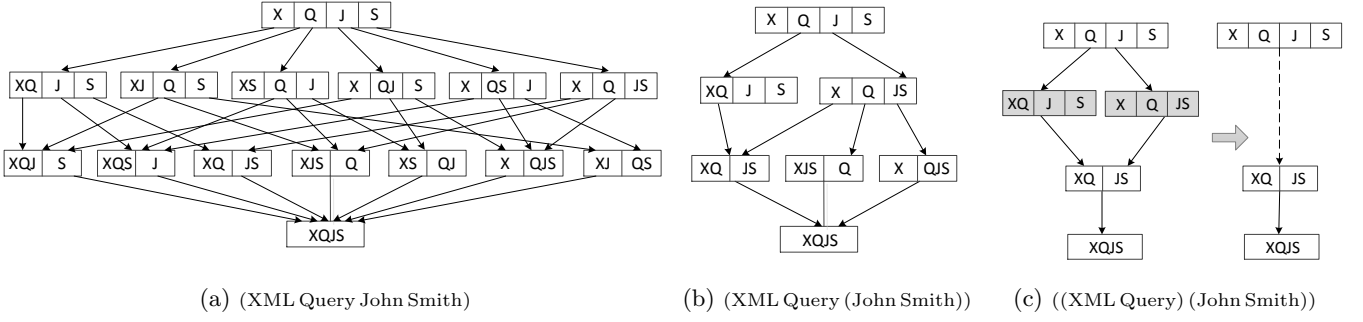

Figure 2: Lattices of keyword partitions for the query (XML Query John Smith) with different cohesiveness relationships

the nested cohesive terms in the query. These partial LCAs contribute with their size to the overall size of the LCA. However, we would like to take also into account how compactly the keyword instances are combined to form partial LCAs for each one of the nested cohesive terms. Consider, for instance, Figure 1 and the query $Q_1 = (\text{XML keyword search (Paul Cooper) (Mary Davis)})$. Article node 2 is an LCA for Q_1 and author node 4 is a partial LCA for the cohesive term (Paul Cooper) contributing with LCA size 0 to the total size of the LCA node 2. The fact that the keyword instances of Paul and Cooper are compactly connected to form a partial LCA of size 0 is also important, as is that the total size of the result is small.

To reflect the importance of intra-cohesive-term proximity, we propose a new ranking scheme which takes also into account the cohesive terms and their sizes in a query result. Our ranking method does not require the preprocessing of the dataset and does not constrain the result representation to specific index terms [4].

We represent each query result as a vector in the cohesive term space for a given query Q . Let Q be a query with m cohesive terms, including the outermost term, i.e., the query itself. Each LCA l_j of a data tree D with respect to Q is represented by the following vector:

$$\vec{l}_j = (C_1 s_{1,j}, C_2 s_{2,j}, \dots, C_m s_{m,j})$$

where C_i is the weight of the term T_i in the query Q with respect to the dataset D and $s_{i,j}$ is the size of the partial LCA for the term T_i within the LCA l_j . Intuitively, the parameter C_i reflects the compactness of the term T_i in the dataset D . That is, how closely the instances of the keywords in T_i appear in the partial LCAs for T_i in the dataset D . Let P_i be the set of the LCAs of a term T_i in D . Then, C_i is defined as follows:

$$C_i = \frac{|P_i|}{1 + \sum_{p \in P_i} \text{size}(p)}$$

The smaller the average size of the LCAs of a term in a dataset D the more compact the term is in D . The vector \vec{l}_j of an LCA l_j is used to define the score of l_j :

$$\text{score}(l_j) = |\vec{l}_j|$$

The query results are ranked in ascending order of their *score*. The weight C_i rewards results which demonstrate small sizes for non-compact terms and penalizes results that demonstrate large sizes for terms, which are expected to be compact.

3. THE ALGORITHM

We designed algorithm CohesiveLCA for keyword queries with cohesiveness relationships. Algorithm CohesiveLCA computes the results of a cohesive keyword query and ranks them in descending order of their LCA size. The idea behind CohesiveLCA is that LCAs of keyword instances in a data tree can result from combining LCAs of subsets of these instances (i.e., partial LCAs of the query) in a bottom-up way in the data tree. CohesiveLCA progressively combines partial LCAs to eventually return full LCAs of instances of all query keywords higher in the data tree. During this process, LCAs are grouped based on the keywords contained in their subtrees. The members of these groups are compared among each other in terms of their size. CohesiveLCA exploits a lattice of partitions of the query keywords.

The lattice of keyword partitions. During the execution of CohesiveLCA, multiple stacks are used. Every stack corresponds to a partition of the keyword set of the query. Each stack entry contains one element (partial LCA) for every keyword subset belonging to the corresponding partition. Stack based algorithms for processing tree structured data push and pop stack entries during the computation according to a preorder traversal of the data tree. Dewey codes are exploited to index stack entries which at any point during the execution of the algorithm correspond to a node in the data tree. Consecutive stack entries correspond to nodes related with parent-child relationships in the data tree.

The stacks used by algorithm CohesiveLCA are naturally organized into a lattice, since the partitions of the keyword set (which correspond to stacks) form a lattice. Coarser partitions can be produced from finer ones by combining two of their members. Partitions with the same number of members belong to the same coarseness level of the lattice. Figure 2a shows the lattice for the keyword set of the query (XML Query John Smith). CohesiveLCA combines partial LCAs following the source to sink paths in the lattice.

Reducing the dimensionality of the lattice. The lattice of keyword partitions for a given query consists of all possible partitions of query keywords. The partitions reflect all possible ways in which query keywords can be combined to form partial and full LCAs. Cohesiveness relationships restrict the ways keyword instances can be combined in a query embedding to form a query result. Keyword instances may be combined individually with other keyword instances to form partial or full LCAs only if they belong to the same term: if a keyword a is “hidden” from a keyword b inside a

term T_a , then an instance of b can only be combined with an LCA of all the keyword instances of T_a and not individually with an instance of a . These restrictions result in significantly reducing the size of the lattice of the keyword partitions as exemplified next.

Figures 2b and 2c show the lattices of the keyword partitions of two queries. The queries comprise the same set of keywords **XML**, **Query**, **John** and **Smith** but involve different cohesive relationships. The lattice of Figure 2a is the full lattice of 15 keyword partitions and allows every possible combination of instances of the keywords **XML**, **Query**, **John** and **Smith**. The query of Figure 2b imposes a cohesiveness relationship on **John** and **Smith**. This modification renders several partitions of the full lattice of Figure 2a meaningless. For instance, in Figure 2b, the partition **[XJ, Q, S]** is eliminated, since an instance of **XML** cannot be combined with an instance of **John** unless the instance of **John** is already combined with an instance of **Smith**, as is the case in the partition **[XJS, Q]**. The cohesiveness relationship on **John** and **Smith** reduces the size of the initial lattice from 15 to 7. A second cohesiveness relationship between **XML** and **Query** further reduces the lattice to the size of 3, as shown in Figure 2c. Note that in this case, besides partitions that are not permitted because of the additional cohesiveness relationship (e.g., **[XJS, Q]**), some partitions may not be productive, which makes them useless. **[XQ, J, S]** is one such partition. The only valid combination of keyword instances that can be produced from this partition is **[XQ, JS]**, which is a partition that can be produced directly from the source partition **[X, Q, J, S]** of the lattice. The same holds also for the partition **[X, Q, JS]**. Thus, these two partitions can be eliminated from the lattice.

Algorithm description. Algorithm CohesiveLCA accepts as input a cohesive keyword query and the inverted lists of the query keywords and returns all LCAs which satisfy the cohesiveness relationships of the query, ranked on their LCA size.

The algorithm begins by building the lattice of stacks needed for the cohesive keyword query processing (line 2). This process will be explained in detail in the next paragraph. After the lattice is constructed, an iteration over the inverted lists (line 3) pushes all keyword instances into the lattice in Dewey code order starting from the source stack of the lattice, which is the only stack of coarseness level 0. For every new instance, a round of sequential processing of all coarseness levels is initiated (lines 6-9). At each step, entries are pushed and popped from the stacks of the current coarseness level. Each stack has multiple columns corresponding to and named by the keyword subsets of the relevant keyword partition. Each stack entry comprises a number of elements one for every column of the stack. The constructor PartialLCA produces a partial LCA element taking as parameters the Dewey code of a node, the term corresponding to a keyword partition, the size of the partial LCA and its provenance. Popped entries contain partial LCAs that are propagated to the next coarseness levels. An entry popped from the sink stack (located in the last coarseness level) contains a full LCA and constitutes a query result. After finishing the processing of all inverted lists, an additional pass over all coarseness levels empties the stacks producing the last results (line 10).

Procedure push() pushes an entry into a stack after ensuring that the top stack entry corresponds to the parent of

the partial LCA to be pushed (lines 11-16). This process triggers pop actions of all entries that do not correspond to ancestors of the entry to be pushed. Procedure pop() is where partial and full LCAs are produced (lines 17-34). When an entry is popped, new LCAs are formed (lines 21-28) and the parent entry of the popped entry is updated to incorporate partial LCAs that come from the popped child entry (lines 29-34). The construction of new partial LCAs is performed by combining LCAs stored in the same entry.

Construction of the lattice. The key feature of CohesiveLCA is the dimensionality reduction of the lattice which is induced by the cohesiveness relationships of the input query. This reduction, as we also show in our experimental evaluation, has a significant impact on the efficiency of the algorithm. Algorithm CohesiveLCA does not naively prune the full lattice to produce a smaller one, but wisely constructs the lattice needed for the computation from smaller component sublattices. This is exemplified in Figure 3.

Consider the data tree depicted in Figure 1 and the query

Algorithm 1: CohesiveLCA

```

1 CohesiveLCA( $Q$ : cohesive keyword query,  $invL$ : inverted
  lists)
2   buildLattice()
3   while  $currentNode \leftarrow getNextNodeFromInvertedLists()$ 
4     do
5        $curPLCA \leftarrow PartialLCA(currentNode.dewey,$ 
6          $currentNode.kw, 0, null)$ 
7        $push(initStack, curPLCA)$ 
8       for every coarsenessLevel  $cL$  do
9         while  $pl \leftarrow next\ partial\ LCA\ of\ cL$  do
10           for every stack  $S$  of  $cL$  containing  $pl.term$  do
11              $push(S, pl)$ 
12   emptyStacks()
13 push( $S$ : stack,  $pl$ : partial LCA)
14   while  $S.dewey$  not ancestor of  $pl.node$  do
15      $pop(S)$ 
16   while  $S.dewey \neq pl.node$  do
17      $addEmptyRow(S)$ 
18    $replaceIfSmallerWith(S.topRow, pl.term, pl.size)$ 
19 pop( $S$ : stack)
20    $p \leftarrow S.pop()$ 
21   if  $S.columns = 1$  then
22      $addResult(S.dewey, p[0].size)$ 
23   if  $S.columns > 1$  then
24     for  $i \leftarrow 0$  to  $S.columns$  do
25       for  $j \leftarrow i$  to  $S.columns$  do
26         if  $p[i]$  and  $p[j]$  contain sizes and
27            $p[i].provenance \cap p[j].provenance = \emptyset$  then
28              $t \leftarrow findTerm(p[i].term, p[j].term)$ 
29              $sz \leftarrow p[i].size + p[j].size$ 
30              $prv \leftarrow p[i].provenance \cup p[j].provenance$ 
31              $pLCA \leftarrow PartialLCA(S.dewey, t, sz, prv)$ 
32   if  $S$  is not empty and  $S.columns > 1$  then
33     for  $i \leftarrow 0$  to  $S.columns$  do
34       if  $p[i].size + 1 < S.topRow[i].size$  then
35          $S.topRow[i].size \leftarrow p[i].size + 1$ 
36          $S.topRow[i].provenance \leftarrow$ 
37            $\{lastStep(S.dewey)\}$ 
38    $removeLastDeweyStep(S.dewey)$ 

```

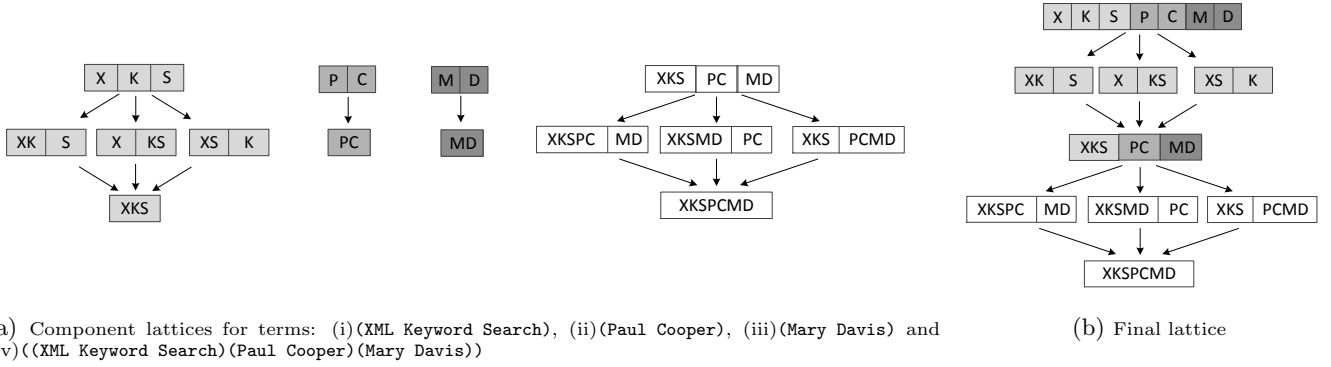

Figure 3: Component and final lattices for the query ((XML Keyword Search) (Paul Cooper) (Mary Davis)))

((XML Keyword Search) (Paul Cooper) (Mary Davis))) issued on this data tree. If each term is treated as a unit, a lattice of the partitions of three items is needed for the evaluation of the query. This is lattice (iv) of Figure 3a. However, the input of this lattice consists of combinations of keywords and not of single keywords. These three combinations of keywords each defines its own lattice shown in the left side of Figure 3a (lattices (i), (ii) and (iii)). The lattice to be finally used by the algorithm CohesiveLCA is produced by composing lattices (i), (ii) and (iii) with lattice (iv) and is shown in Figure 3b. This is a lattice of only 9 nodes, whereas the full lattice for 7 keywords has 877 nodes.

Function `buildLattice()` constructs the lattice for evaluating a cohesive keyword query. This function calls another function `buildComponentLattice()` (line 8). Function `buildComponentLattice()` (lines 18-21) is a recursive and builds all lattices for all terms which may be arbitrarily nested. The whole process is controlled by the *controlSets* variable which stores the keyword subsets admissible by the input cohesiveness relationships. This variable is constructed by the procedure `constructControlSet()` (lines 9-17).

3.1 Algorithm analysis

Algorithm CohesiveLCA processes the inverted lists of the keywords of a query exploiting the cohesiveness relationships to limit the size of the lattice of stacks used. The size of a lattice of a set of keywords with k keywords is given by the Bell number of k , B_k , which is defined by the recursive formula:

$$B_{n+1} = \sum_{i=0}^n \binom{n}{i} B_i, \quad B_0 = B_1 = 1$$

In a cohesive query containing t terms the number of sublattices is $t + 1$ counting also the sublattice of the query (outer term). The size of the sublattice of a term with cardinality c_i is B_{c_i} . A keyword instance will trigger in the worst case an update to all the stacks of all the sublattices of the terms in which the keyword participates. If the maximum nesting depth of terms in the query is n and the maximum cardinality of a term or of the query itself is c , then an instance will trigger $O(nB_c)$ stack updates. For a data tree with depth d , every processing of a partial LCA by a stack entails in the worst case d pops and d pushes, i.e., $O(d)$. Every pop from a stack with c columns implies in the worst case $c(c-1)/2$

Function buildLattice

```

1 buildLattice( $Q$ : query)
2    $\text{singletonTerms} \leftarrow \{\text{keywords}(Q)\}$ 
3    $\text{stacks.add}(\text{createSourceStack}(\text{singletonTerms}))$ 
4   constructControlSet( $Q$ ) for every control set cset in
    controlSets with not only singleton keywords do
5      $\text{stacks.add}(\text{createSourceStack}(\text{cset}))$ 
6   for every s in stacks do
7     buildComponentLattice( $s$ )
8
9 constructControlSet( $qp$ : query subpattern)
10   $c \leftarrow \text{new Set}()$ 
11  for every singleton keyword k in s do
12     $c.add(k)$ 
13  for every subpattern sqp in s do
14     $\text{subpatternTerm} \leftarrow \text{constructControlSet}(\text{sqp})$ 
15     $c.add(\text{subpatternTerm})$ 
16   $\text{controlSets.add}(c)$ 
17  return newTerm( $c$ )
18

```

combinations to produce partial LCAs and c size updates to the parent node, i.e., $O(c^2)$. Thus, the time complexity of CohesiveLCA is given by the formula:

$$O(dnc^2B_c \sum_{i=1}^c |S_i|)$$

where S_i is the inverted list of the keyword i . The maximum term cardinality for a query with a given number of keywords depends on the number of query terms. It is achieved by the query when all the terms contain one keyword and one term with the exception of the innermost nested term which contains two keywords. Therefore, the maximum term cardinality is $k - t - 1$ and the maximum nesting depth is t . Thus, the complexity of CohesiveLCA is:

$$O(dt(k-t-1)^2B_{k-t-1} \sum_{i=1}^k |S_i|)$$

This is a parameterized complexity which is linear to the size of the input (i.e., $\sum |S_i|$) for a constant number of keywords and terms.

4. EXPERIMENTAL EVALUATION

We implemented our algorithm and we experimentally studied: (a) the effectiveness of the CohesiveLCA semantics and (b) the efficiency of the CohesiveLCA algorithm.

The experiments were conducted on a computer with a 1.6GHz dual core Intel Core i5 processor running Mac OS 10.8. The code was implemented in Java.

4.1 Datasets and queries

We used four real datasets: the bibliographic dataset DBLP¹, the astronomical dataset NASA², the Protein Sequence Database (PSD)³ and the sports statistics dataset Baseball⁴. We also used a synthetic dataset, the benchmark auction dataset XMark⁵. These datasets cover different application areas and display various characteristics. Table 1 shows their statistics.

The DBLP is the largest and XMark the deepest dataset. For the effectiveness experiments, we used the real datasets DBLP, PSD, NASA and Baseball. For the efficiency evaluation, we used the DBLP, XMark and NASA datasets in order to test our algorithm on data with different structural and size characteristics. The keyword inverted lists of the parsed datasets were stored in a MySQL database.

We selected five cohesive keyword queries for each one of the four real datasets with an intuitive meaning. The queries display various cohesiveness patterns and involve 3-6 keywords. They are listed in Table 2. The binary relevance (correctness) and graded relevance assessments of all the LCAs were provided by five expert users. For the graded relevance, a 4-value scale was used with 0 denoting irrelevance. In order to avoid the manual assessment of each LCA in the XML tree, which is unfeasible because the LCAs are usually numerous, we used the tree patterns that the query instances of these LCAs define in the XML tree. These patterns show how the query keyword instances are combined under an LCA to form an MCT, and how the LCA is connected to the root of the data tree. Since they are bound by the schema of a data set they are in practice much less numerous than the LCAs. The relevance of an LCA is the maximum relevance of the patterns with which the query instances of the LCA comply.

4.2 Effectiveness of cohesive semantics

In this section we evaluate the effectiveness of cohesive semantics both as a filtering and as a ranking mechanism.

Filtering cohesive semantics. We compared the CohesiveLCA semantics with the *smallest* LCA (SLCA) [18, 40,

37, 10], *exclusive* LCA (ELCA) [16, 41, 42], *valuable* LCA (VLCA) [11, 20] and *meaningful* LCA [24] (MLCAs) filtering semantics. These are the best known filtering semantics discussed in the literature. An LCA is an SLCA if it is not an ancestor of another LCA in the data tree. An ELCA is an LCA of a set of keyword instances which are not in the subtree of any descendant LCA. An LCA is a VLCA if it is the root of an MCT which does not contain any label twice except when it is the label of two leaf nodes of the MCT. The MLCA semantics requires that for any two nodes n_a and n_b labeled by a and b , respectively, in an MCT, no node n'_b labeled by b exists which is more closely related to n_a (i.e., $lca(n_a, n'_b)$ is descendant of $lca(n_a, n_b)$). SLCA and ELCA semantics are based purely on structural characteristics, while VLCA and MLCA take also into account the labels of the nodes in the data tree.

Table 3 displays the number of results for each query and approach on the DBLP, PSD, NASA and Baseball datasets. Notice that, with the exception of SLCA and ELCA which satisfy a containment relationship ($SLCA \subseteq ELCA$), all other approaches are pairwise incomparable. That is, one might return results that the other excludes and vice versa. The CohesiveLCA approach returns all the results that satisfy the cohesiveness relationships in the query. Since these relationships are imposed by the user, any additional result returned by another approach is irrelevant. For instance, for query Q_5^P , only 3 results satisfy the cohesiveness relationships of the user, and therefore, SLCA, VLCA, MLCA return at least 37 and ELCA at least 40 irrelevant results.

The CohesiveLCA semantics is a ranking semantics and ranks the results in layers based on their size. In order to

⁵<http://www.xml-benchmark.org>

Figure 4: Precision and \mathcal{F} -measure of top size Cohesive LCA, SLCA and ELCA filtering semantics

compare its effectiveness with filtering semantics we restrict the results to the top layer (top-1-size results). Recall that these are the results with the minimum LCA size. The comparison is based on the widely used *precision* (P), *recall* (R) and \mathcal{F} -measure = $\frac{2P \times R}{P+R}$ metrics [4]. Figure 4 depicts the results for the five semantics on the four datasets. Since all approaches demonstrate high recall, we only show the precision and \mathcal{F} -measure results in the interest of space.

The diagram of Figure 4a shows that CohesiveLCA largely

outperforms the other approaches in all cases. Top-1-size CohesiveLCA shows perfect precision for all queries on all datasets. This is not surprising since, CohesiveLCA can benefit from cohesiveness relationships specified by the user to exclude irrelevant results. CohesiveLCA also shows perfect \mathcal{F} -measure on the DBLP and Baseball datasets. Its \mathcal{F} -measure on the PSD and NASA datasets is lower. This is due to the following reason: contrary to the shallow DBLP and Baseball datasets, the PSD and NASA datasets are deep and complex with a large amount of text in their nodes. This complexity leads to results of various sizes for most of the queries. Some of the relevant results are not of minimum size and they are missed by top-1-size CohesiveLCA. Nevertheless, any relevant result missed by top-1-size CohesiveLCA is retrieved by CohesiveLCA which returns all relevant results, as one can see in Table 4.

Table 4 summarizes the precision, recall and \mathcal{F} -measure values of the queries on all four datasets. The table displays values for the five filtering semantics but also for the CohesiveLCA semantics (without restricting the size of the results). Both CohesiveLCA and top-1-size CohesiveLCA outperform the other approaches in all three metrics. Top-1-size CohesiveLCA demonstrates perfect precision while CohesiveLCA with a slightly lower precision guarantees perfect recall. These remarkable results on the effectiveness of our approach are obtained thanks to the cohesiveness relation-

dataset	query	# of results				
		CohesiveLCA	SLCA	ELCA	VLCA	MLCA

Figure 5: Performance of CohesiveLCA for queries with 10, 15 and 20 keywords varying the number of instances

ships which are provided effortlessly by the user.

Ranking cohesive semantics We evaluated our result ranking scheme by computing the Mean Average Precision (MAP) [4] and the Normalized Discounted Cumulative Gain (NDCG) [4] on the queries of Table 2. MAP is the average of the individual precision values that are obtained every time a correct result is observed in the ranking of the query. If a correct result is never retrieved, its contributing precision value is 0. MAP penalizes an algorithm when correct results are missed or incorrect ones are ranked highly. Given a specific position in the ranking of a query result set, the Discounted Cumulative Gain (DCG) is defined as the sum of the grades of the query results until this ranking position, divided (discounted) by the logarithm of that position. The DCG vector of a query is the vector of the DCG values at the different ranking positions of the query result set. Then, the NDCG vector is the result of normalizing this vector with the vector of the perfect ranking (i.e., the one obtained by the grading of the result set by the experts). NDCG penalizes an algorithm when the latter favors poorly graded results over good ones in the ranking.

MAP (%)			
DBLP	PSD	NASA	Baseball
94	99	94	97
NDCG (%)			
DBLP	PSD	NASA	Baseball
100	99	98	100

Table 5: MAP and NDCG measurements on the four datasets for the queries of Table 2

Table 5 shows the MAP and NDCG values of the cohesive ranking on the queries of Table 2. The excellent values of NDCG show that the ranking in ascending order of the scores of the result LCAs (which take into account the partial LCA sizes and the cohesive term weights) is very close to the correct ranking of the results provided by the expert users. Most MAP values are slightly inferior to 100. This means that a small number of non-relevant LCAs are ranked higher than some relevant. However, the high NDCG values, guarantee that these LCAs are not highly located in the total rank.

4.3 Efficiency of the CohesiveLCA algorithm

In order to study the efficiency of our algorithm we run

experiments to measure: (a) its performance scalability on the dataset size, (b) its performance scalability on the query maximum term cardinality and (c) the improvement in efficiency over previous approaches. We used collections of queries with 10, 15 and 20 keywords issued against the DBLP, XMark and NASA datasets. For each query size, we formed 10 cohesive query patterns. Each pattern involves a different number of terms of different cardinalities nested in various depths. For instance, a query pattern for a 10-keyword query is $(xx((xxxx)(xxxx)))$. We used these patterns to generate keyword queries on the three datasets. The keywords were chosen randomly. In order to stress our algorithm, they were selected among the most frequent ones. In particular, for each pattern, we generated 10 different keyword queries and we calculated their average evaluation time. We generated, in total, 100 queries for each dataset. For each query, we run experiments scaling the size of each keyword inverted list from 100 to 1000 instances with a step of 100 instances.

Performance scalability on dataset size. Figure 5 shows how the computation time of CohesiveLCA scales when the total size of the query keyword inverted lists grows. Each plot corresponds to a different query size (10, 15 or 20 keywords) and displays the performance of CohesiveLCA on the three datasets. Each curve corresponds to a different dataset and each point in a curve represents the average computation time of the 100 queries that conform to the 10 different patterns of the corresponding query size. Since the keywords are randomly selected among the most frequent ones this figure reflects the performance scalability with respect to the dataset size.

All plots clearly show that the computation time of CohesiveLCA is linear on the dataset size. This pattern is followed, in fact, by each one of the 100 contributing queries. In all cases, the evaluation times on the different datasets confirm the dependence of the algorithm’s complexity on the maximum depth of the dataset: the evaluation on DBLP (max depth 5) is always faster than on NASA (max depth 7) which in turn is faster than on XMark (max depth 11).

It is interesting to note that our algorithm achieves interactive computation times even with multiple keyword queries and on large and complex datasets. For instance, a query with 20 keywords and 20,000 instances needs only 20 sec to be computed on the XMark dataset. These results are achieved on a prototype without the optimizations of a commercial keyword search system. To the best of our knowledge, there is no other experimental study in the relevant literature that considers queries of such sizes.

Performance scalability on max term cardinality. As we showed in the analysis of algorithm CohesiveLCA (Section 3.1), the key factor which determines the algorithm’s performance is the maximum term cardinality in the input query. The maximum term cardinality determines the size of the largest sublattice used for the construction of the lattice ultimately used by the algorithm (see Figure 3). This dependency is confirmed in the diagram of Figure 6. We used queries of 10, 15 and 20 keywords with a total number of 6000 instances each on the DBLP dataset. The x axis shows the maximum term cardinality of the queries. The computation time shown by the bars (left y axis) is averaged over all the queries of a query size with the corresponding maximum cardinality. The curve displays the evolution of the size of the largest sublattice as the maximum term cardinality increases. The size of the sublattice is measured by the number of the stacks it contains (right y axis).

It is interesting to observe that the computation time depends primarily on the maximum term cardinality and to a much lesser extent on the total number of keywords. For instance, a query of 20 keywords with maximum term cardinality 6 is computed much faster than a query of 10 keywords with maximum term cardinality 7. This observation shows that as long as the terms involved are not huge, CohesiveLCA is able to efficiently compute queries with a very large number of keywords.

Performance improvement with cohesive relationships. In order to study the improvement in execution time brought by the cohesiveness relationships to previous algorithms, we compare CohesiveLCA with algorithms which compute a superset of LCAs and rank them with respect to their size. In these cases, since taking into account cohesiveness relationships filters out irrelevant results, the quality of the answer is improved. It is not meaningful to compare with other algorithms since their result sets are incomparable to that of CohesiveLCA (no result set is inclusive of the other) and they do not rank their results on their size. For the experiments we used the DBLP dataset—the results on the other datasets are similar.

There are two previous algorithms that can compute the full set of LCAs with their sizes: algorithm LCAsz [13, 14] and algorithm SA [17]. LCAsz is an algorithm that computes all the LCAs with their sizes which, similarly to CohesiveLCA, exploits a lattice of stacks. The SA algorithm [17]

Figure 6: Performance of CohesiveLCA on queries with 6000 keyword instances for different maximum term cardinalities on the DBLP dataset

Figure 7: Improvement of CohesiveLCA over LCAsz varying the number of query keywords

computes all LCAs together with a compact form of their matching MCTs, called GDMCTs, which allows determining the size of an LCA. We implemented algorithm SAOne [17] which is a more efficient version of SA since it computes LCAs without explicitly enumerating all the GDMCTs.

Figure 7 compares the execution time of LCAsz and CohesiveLCA in answering keyword queries on the DBLP dataset varying the number of keywords. The execution time of LCAsz is averaged over 10 random queries with frequent keywords. Various cohesiveness relationships patterns were defined for CohesiveLCA (their number depends on the total number of keywords), and for each one of them 10 random queries of frequent keywords were generated. The execution time for CohesiveLCA is averaged over all the queries generated with the same number of keywords. In all cases, each keyword inverted list was restricted to 1000 instances.

As we can see in Figure 7, CohesiveLCA outperforms LCAsz. The improvement in performance reaches an order of magnitude for 6 keywords and increases for 7 keywords or more. Further, CohesiveLCA scales smoothly compared to LCAsz since, as explained above, its performance is dependent on the maximum term cardinality, as opposed to the total number of keywords that determines the performance of LCAsz.

Figure 8 compares the execution times of CohesiveLCA, LCAsz and SAOne for queries of 6 keywords varying the total number of keyword instances. The measurements are average execution times over multiple random queries and cohesiveness relationships patterns (for CohesiveLCA) as in the previous experiment. As one can see, CohesiveLCA clearly outperforms all previous approaches. LCAsz, in turn, largely outperforms SAOne which also scales worse than the other two

5. RELATED WORK

Keyword queries facilitate the user with the ease of freely forming queries by using only keywords. Approaches that evaluate keyword queries are currently very popular especially in the web where numerous sources contribute data often with unknown structure and where end users with no specialized skills need to find useful information. However, the imprecision of keyword queries results often in low precision and/or recall of the search systems. Some approaches combine structural constraints with keyword search [11]. Other approaches try to infer useful structural information implied by keyword queries by exploiting statistical information of the query keywords on the underlying datasets [5, 22, 38, 25, 7]. These approaches require a minimum knowledge

Figure 8: CohesiveLCA scaling comparison with other approaches for queries of 6 keywords

of the dataset or a heavy dataset preprocessing in order to be able to accurately assess candidate keyword query results. A great amount of previous work elaborates on keyword query evaluation on graph data (e.g., RDF databases or graphs extracted from Relational databases) [18, 12, 30, 7]. However, the focus of this work is on tree data.

The task of locating the nodes in a data tree which most likely match a keyword query has been extensively studied in [11, 18, 17, 20, 27, 41, 19, 22, 10, 13, 6, 23, 26, 38, 32, 2, 14, 1]. All these approaches use LCAs of keyword instances as a means to define query answers. The *smallest* LCA (SLCA) semantics [40, 28] validates LCAs that do not contain other descendant LCAs of the same keyword set. A relaxation of this restriction is introduced by *exclusive* LCA (ELCA) semantics [16, 41], which accepts also LCAs that are ancestors of other LCAs, provided that they refer to a different set of keyword instances.

In a slightly different direction, semantic approaches account also for node labels and node correlations in the data tree. *Valuable* LCAs (VLCAs) [11, 20] and *meaningful* LCAs (MLCAs) [24] aim at “guessing” the user intent by exploiting the labels that appear in the paths of the subtree rooted at an LCA. All these semantics are restrictive and depending on the case, they may demonstrate low recall rates as shown in [38].

The efficiency of algorithms that compute LCAs as answers to keyword queries depend on the query semantics adopted. By design they exploit the adopted filtering semantics to prune irrelevant LCAs early on in the computation. Stack based algorithms are naturally offered to process tree data. In [16] a stack-based algorithm that processes inverted lists of query keywords and returns ranked ELCAs was presented. This approach ranks also the query results based on precomputed tree node scores inspired by PageRank [8] and IR style keyword proximity in the subtrees of the ranked ELCAs. An algorithm that computes all the LCAs ranked on LCA size is presented in [13, 14]. In [40], two efficient algorithms for computing SLCAs are introduced, exploiting special structural properties of SLCAs. This approach also introduces an extension of the basic algorithm, so that it returns all LCAs by augmenting the set of already computed SLCAs. Another algorithm for efficiently computing SLCAs for both AND and OR keyword query semantics is developed in [37]. The Indexed Stack [41] and the Hash Count [42] algorithms improve the efficiency of [16] in computing ELCAs. Finally, [5, 6] elaborate on sophisticated ranking of candidate LCAs aiming primarily on effective keyword

query answering.

Filtering semantics are often combined with (i) structural and semantic correlations [16, 21, 10, 38, 11, 2], (ii) statistical measures [16, 11, 21, 10, 22, 38] and (iii) probabilistic models [38, 32, 23] to perform a ranking to the results set. Nevertheless, such approaches require expensive preprocessing of the dataset which makes them impractical in the cases of fast evolving data and streaming applications.

The most well known ranking models in the literature of IR assume term independency [4]. Extensions of the basic ranking models such as the generalized vector model [39] and the set based vector model [34] represent queries and documents using sets of terms. However, the ranking scheme in these models requires preprocessing of the data collection to compute $tf * idf$ style metrics for a representative subset of the term vocabulary. The work in [35] enhances keyword queries with structure to extract information from knowledge bases. However, their approach targets graph databases with semantic information and their queries are schema dependent. In contrast, our cohesive queries only contain groupings of the keywords expressing cohesiveness relationships which are not related to any schema construct. As such, the same cohesive query can be issued against any type of dataset (flat text documents, trees, graphs, etc.).

6. CONCLUSION

Current approaches for assigning semantics to keyword queries on tree data cannot cope efficiently or effectively with the large number of candidate results and produce answers of low quality. The convenience and simplicity offered to the user by the keyword queries cannot offset this weakness. In this paper, we claim that the search systems cannot guess the user intent from the query and the characteristics of the data to produce high quality answers on any type of dataset and we introduce a cohesive keyword query language which allows the users to naturally and effortlessly express cohesiveness relationships on the query keywords. We design an algorithm which builds a lattice of stacks to efficiently compute cohesive keyword queries and rank the results leveraging cohesiveness relationships to reduce the lattice dimensionality. A theoretical analysis and experimental evaluation show that our approach outperforms previous approaches in producing answers of high quality and scales smoothly succeeding to evaluate efficiently queries with a very large number of frequent keywords on large and complex datasets where previous algorithms for flat keyword queries fail.

We are currently working on alternative ways for defining semantics for cohesive keyword queries on tree data and in particular in defining skyline semantics which considers all the cohesive terms of a query in order to rank the query results.

ABSTRACT

XML and JSON have become the default formats to exchange the information for web application or within enterprises. Keyword Search over XML data has been motivated by the need to relieve users from writing difficult XQueries since otherwise users are required to know the complex XML schema. In existing XML keyword search techniques the XML nodes returned for a keyword query are the Lowest Common Ancestor (LCA) nodes for the query keywords. In this paper, we argue that the LCA based techniques *still* require users to be well versed with the XML schema and also the data to be able to obtain meaningful query results.

To address these shortcomings, we present a novel system, Generic Keyword Search (GKS), - for a given keyword query Q , instead of identifying (and returning information) only from LCA nodes, GKS returns ‘meaningful’ information from *any* XML node, which contains a subset of keywords in the search query Q . GKS response includes LCA nodes, if any, that would have been returned by LCA based techniques.

GKS is also able to find highly relevant keywords and XML schema elements, deeper analytical insights - called *DI* - in the XML data *in the context of the user query*. *DI* enables users to navigate the XML data and to refine their queries even if they are not familiar with the data and the schema. Our experiments on real data sets show that GKS is able to return highly relevant responses to keyword queries efficiently.

1. INTRODUCTION

Semi-structured data, e.g. XML and JSON, are default formats to represent and exchange data within and across enterprises and web [18]. XML data is represented as a labeled, ordered tree T as shown in Figure 1(i). The nodes in T are either XML schema elements or text nodes. In response to a given keyword query, XML keyword search systems return one or more nodes in T , each of which is a Lowest Common Ancestor (LCA) node for *all* the query keywords in the XML data tree T [2][5][6][16][17][4]. For instance, in Figure 1, node x_2 is the LCA node for query Q_1 . We refer to XML keyword search technique that return LCA nodes in the XML tree, in response to a given keyword query, as *LCA based techniques*. LCA based techniques follow the AND-semantics, i.e., each LCA node contains at least one instance of each query keyword [4].

1.1 Motivation

For a given keyword query $Q = \{k_1, \dots, k_n\}$ ($|Q| = n$), instead of identifying LCA nodes and returning information only from these nodes, Generic Keyword Search (GKS) returns *any* node in the labeled tree T , if it contains s or more keywords in the search query Q ($s \leq n$). More formally, the GKS problem is defined as follows: For a keyword query Q , an integer $s \geq 1$, search returns all the XML nodes which contain at least $\min(s, |Q|)$, keywords from Q . The set of XML nodes returned by GKS in response to query Q is denoted by $R_Q(s)$. $|R_Q(s_1)| \leq |R_Q(s_2)|$ if $s_1 > s_2$ (cf. Section 2.2).

There are many notions of LCA nodes in the literature but SLCA (Smallest LCA) [13] and ELCA (Exclusive LCA) [17], are most widely used. An SLCA node contains all the query keywords in its sub-tree and there is no node in its sub-tree which contains all the keywords. An ELCA set of nodes is a superset of the SLCA nodes. In Figure 1, for query Q_1 , node x_1 is an ELCA node but not an SLCA node due to the presence of x_2 in its sub-tree. In the figure, k_i is an instance of keyword k (e.g. a_s are instances of a). For different notions of LCA nodes, progressively faster algorithms have been proposed to retrieve them [16]. The nodes in GKS response set follow the semantics of SLCA.

As pointed out by the authors of [19] “LCA based techniques work poorly for documents having *irregular schema* that have *missing elements*” because the schema allows certain XML nodes to be optional. Further noting that if a document is not complete, the resulting output could be different from the intended output. Authors of [19] develop an alternate approach whose basic premise is: for a given keyword search query, specific XML node types are targeted [15][19]. However, if the document has “missing XML elements”, nodes other than targeted nodes could also be returned due to the constraint on LCA based techniques (only LCA nodes are returned for the keyword query). Clearly, the motivation for [19] highlights that for LCA based techniques a) users need to be aware of the schema (i.e., users need to be aware which XML nodes to target); b) query keywords must be chosen by taking into account the semantic relationship between them (query must be formed such that the target nodes could be returned); and c) users need to be aware of the keywords in the XML document(s) and their distribution in XML tree T (otherwise nodes other than targeted nodes could become LCA nodes). In other words, in order to be able to effectively search the data using LCA based techniques, users have to be well acquainted with the data and the schema.

AND-semantics constraints underlying LCA based techniques are further highlighted by the following example:

Example 1: Consider keyword queries Q_1, Q_2, Q_3 , on the XML document in Figure 1(i). Each leaf node in the XML document is a text node (text node is an XML element directly containing its value). We have represented the document as shown in Figure 1(i) for brevity. Response of SLCA and ELCA based algorithms are

shown in Table 1. For query Q_3 , even though the user is able to select all the keywords present in the document, the response of LCA algorithms is root $\{r\}$. ‘r’ is not a meaningful response as it is available to the user even in the absence of any query.

Figure 1. Labeled XML data tree and a set of queries.

Table 1. Nodes returned for different queries on labeled XML tree by different keyword search algorithms

Queries	GKS (ranked)	ELCA	SLCA
$Q_1, s= Q_1 $	$\{x_2\}$	$\{x_1, x_2\}$	$\{x_2\}$
$Q_2, s=2$	$\{x_2\}, \{x_3\}$	NULL	NULL
$Q_3, s=2$	$\{x_2\}, \{x_3\}, \{x_4\}$	$\{r\}$	$\{r\}$

Therefore, to construct meaningful queries, users need to know the keywords distribution in the document. To know the keyword distribution, it is imperative to know the semantic relationship between query keywords. In order to be aware of the semantic relationship between the query keywords, users must know the schema of the XML repository. Users must also know the schema to form the query such that targeted XML nodes are returned.

MESSIAH [19] addresses the issues arising due to the AND-semantics of LCA based techniques. Its authors propose an efficient FSLCA algorithm to identify intended nodes, in case of missing XML elements in the data. MESSIAH addresses the missing element problem, if the data is ‘imperfect’. However, the issues of ‘missing data elements’ is still not handled in [19] if the user query is ‘imperfect’. For instance, if a query keyword occurs in the wrong sub-tree, it is difficult to determine the intended return nodes. Hence, for a keyword query, possibly containing semantically uncorrelated keywords, nodes other than targeted nodes will be returned by [19] even if the missing XML elements are identified.

Consider the following scenario: User starts with query Q_2 and Q_3 (shown in Figure 1). GKS returns a set of XML nodes to the user, as shown in Table 1, which contain a significant fraction of the query keywords but not necessarily all the query keywords ($s=2$). Besides returning these nodes, let us say, GKS system also suggests to the user that query Q_2 can be morphed to $\{a, b, c\}$ or $\{a, b, d\}$ from $\{a, b, e\}$. The user may not be aware of the existence of the keywords $\{‘c’, ‘d’\}$ or their relevance in the context of the query. Similarly, for Q_3 , the system suggests that query be partitioned into $\{a, b, c\}$ and $\{a, b, d\}$. Such refinements of the user queries are non-trivial. Overall, we are motivated by the following goals 1) to relax the need for users to know the XML data precisely; this enables them to browse the XML data in a manner similar to web search; 2) to relax the need for users to know the XML schema as user queries can be refined progressively (as for query Q_3).

1.2 Generic Keyword Search

In this paper, we introduce a novel concept of **Generic Keyword Search (GKS)** over XML data to address the shortcomings listed above. It enables the users to navigate XML data with ease, as demonstrated with the help of an example on real data below run on the implemented GKS system [20]:

Example 2: We have a DBLP dataset with more than 2.5 million articles. A query $Q_d = \{\text{"Peter Buneman" "Wenfei Fan" "Scott Weinstein" "Prithviraj Banerjee"}\}$ is run on this dataset. The user is most likely interested in articles jointly written by these authors. In its response, a total of 234 articles (for $s=1$) are found by GKS, i.e., GKS return all the articles by any of the authors in the keyword query since $s=1$.

Since the response of GKS contains a large number of XML nodes (i.e., $\langle \text{inproceedings} \rangle$), with different XML nodes in the response containing different number of authors, the results are ranked such that the more relevant XML nodes are ranked higher (cf. Section 5). For query Q_d , the $\langle \text{inproceedings} \rangle$ nodes with higher number of query keywords (i.e., author names) in their sub-tree are likely to be ranked higher. We use just $\langle ip \rangle$ for $\langle \text{inproceedings} \rangle$ later on.

In the DBLP dataset, there is no article jointly written by Prithviraj Banerjee with any of the remaining authors. Of the five articles jointly written by the remaining three authors in DBLP dataset, 4 were returned as top 4 results in the ranked list of XML nodes by GKS. The remaining article was also in top 10 (it was ranked lower due to many co-authors, details Section 5). In the context of this example, we now explain how GKS overcomes the shortcomings of the LCA based techniques:

GKS relaxes the need for users’ familiarity with the contents:

For the given query, an LCA based technique would have returned $\{\text{DBLP root}\}$, containing millions of articles as the response due to the presence of one “wrong” keyword ‘Prithviraj Banerjee’ in the query. On the other hand, GKS produced a more “meaningful” response in the presence of “wrong” query keyword(s). This helps the users as follows;

a) With GKS, users can navigate the XML data without complete awareness with underlying data (for LCA based techniques, users need to know, which authors have published articles together). GKS returns a ranked list of most relevant XML nodes, in the context of the query, considerably enhancing the users’ ability to search the data with high precision and recall.

b) More importantly, even when users are able to formulate the query precisely, there is a lot of information which could be of their interest, which are not returned by LCA based techniques due to the constraint that *only* LCA nodes must be returned. For instance, in Example 2, the articles by a large enough subset of authors in the query Q_d could also be of interest to the user in the context of the query. Exposing such results in the data helps users navigate the data as well as to refine their queries (cf. Section 6.1).

GKS relaxes the need for users’ familiarity with the schema:

GKS identifies the XML nodes, which are not necessarily LCA nodes but that could be of interest to the user in the context of the query. This ability of GKS can be exploited to discover most relevant keywords and their semantics in the underlying XML data, in the context of the user query. This information is called *deeper analytical insights* or *DI*. For the query in Example 2, GKS exposes $\langle ip: \text{journal: SIGMOD Record} \rangle$, $\langle ip: \text{year: 2001} \rangle$, $\langle ip: \text{author: Alok N Choudhary} \rangle$ and $\langle ip: \text{booktitle: ICPP} \rangle$, etc., as *DI* from the XML data in the context of the query (GKS returns a well-constructed XML chunk. Truncated representation is due to lack of space). *DI* exposes the most relevant journals, year and authors in the query response. The user may not be aware of these keywords or their relevance in the context of the query.

DI is defined formally in Section 2.3 (Def. 2.3.1). Discovery of *DI* (Section 6) enhances the users’ ability to navigate the data even if they are unaware of the schema details and the semantic relationship between the various data keywords. To discover *DI*,

we exploit the XML schema, embedded in the structure of the XML data, in the context of a user query. A novel node categorization model is proposed that identifies certain XML node types as Least Common Entity nodes or LCE nodes (cf. Section 2.2). LCE nodes are central to our methodology to discover *DI*. A subset of XML nodes $E_Q \subseteq R_Q(s)$ in GKS response for query Q can be Least Common Entity (LCE) nodes; $0 \leq |E_Q| \leq |R_Q(s)|$. For an XML node u containing a sub-set of query keywords (of size $\geq s$) in its sub-tree, its corresponding LCE node will be either u itself or its ancestor.

In Example 2, $\langle ip \rangle$ node is an LCE node. GKS exposes the semantics of the *DI* keywords, i.e., 2001 is a $\langle year \rangle$ with the aid of XML elements on the path from the root of LCE node $\langle ip \rangle$ till the keyword “2001”. Semantics are important as in a different context, 2001 could be a street number. Query keywords, either XML element names or text keywords, may carry different meaning in different context [9]. Exposing the relevant keywords and their semantic meaning helps users refine their queries in the absence of knowledge about the schema and the data.

GKS returns meaningful response: The meaningfulness of the results of a search query is defined by their recall and precision. In LCA based search, a keyword query typically targets XML nodes belonging to specific schema elements \mathbf{E} in the associated XML schema [19]. $\langle E \rangle \in \mathbf{E}$ is an XML schema element. The target nodes are the LCA nodes of the query keywords. If the returned LCA nodes are of targeted schema element type(s), it constitutes a meaningful response. For the query Q_d in Example 2, the meaningful LCA nodes for this query are all of type $\langle ip \rangle$ in the corresponding XML schema.

However, due to imperfect data with missing XML elements or due to imperfect query, LCA based techniques often return LCA nodes other than the target XML elements type [19]. For instance, for query Q_d , LCA based techniques will return the DBLP root. A more meaningful response is a ranked list of articles, jointly written by a sub-set of authors in the query, i.e., returning nodes of same type, which were targeted. For GKS system, all the XML nodes that contain any subset of keywords in a query (of size $\geq s$) are returned. Therefore, recall of GKS is likely to be high since GKS query response is likely to have XML nodes which are instances of target XML schema element in \mathbf{E} for a user query Q (any XML node containing $s \leq |Q|$ keywords in its sub-tree is returned).

In the context of a keyword query, the relevance of a XML node is high if it contains a large fraction of query keywords. The precision of the GKS system will be high if the most relevant XML nodes in the GKS query response are ranked higher. We present a novel ranking methodology (Section 4) to ensure high precision.

1.3 Research Challenges and Contributions

Similar to a web search engine, Generic Keyword Search has the twin objectives of: a) locating the most relevant XML nodes for the given keyword query efficiently; and b) ordering the search results to rank more meaningful results higher.

GKS has three primary challenges; 1) **Efficiency** –GKS has much larger search space as opposed to LCA based techniques (Lemma 3). Therefore, a major challenge for GKS is to be able to retrieve the relevant nodes efficiently (Section 4); 2) **Ranking** – Number of XML nodes retrieved by GKS could be large and the structure of the different XML nodes in the search results could be different. Therefore, it is imperative to rank the nodes such that more meaningful and relevant nodes are ranked higher (Section 5); 3) **Analysis** - GKS aims to enable the users to refine their queries without needing them to be familiar with schema and data. GKS

meets this challenge by exposing relevant keywords in the data and their semantics in the context of the user query (Section 6).

In this paper, we make the following contributions:

1. Existing XML Keyword Search techniques work within LCA framework. We introduce Generic Keyword Search (GKS) that enables XML search beyond LCA framework.
2. We propose a XML node categorization model. With the aid of this model, we expose most relevant XML elements and data keywords, called *DI*, in the context of a given keyword query. Users can refine their query with the aid of *DI*. *DI* is discovered *because* GKS does not impose the LCA constraint.
3. We introduce a ranking methodology to rank more meaningful XML nodes, retrieved by GKS, higher. Node ranking is further exploited for *DI* discovery.
4. We present an evaluation of GKS system on real data sets. Our results show that GKS is able to return highly relevant response for the given keyword queries efficiently. We further show that our system is able to find highly relevant *DI* that enables the users to navigate the XML data seamlessly.

The organization of the paper is as follows. Section 2 introduces the GKS node categorization model along with the definitions of LCE nodes, *DI* and the GKS indexing structure. Related work is presented in Section 3. Our methodology to identify the relevant XML nodes efficiently is the subject of Section 4. In Section 5, we present a novel XML node ranking methodology. In Section 6, we discuss our mechanism to discover *DI*. In Section 7, we present experimental results followed by conclusion in Section 8.

2. XML NODE CATEGORIZATION AND DEFINITIONS

In this section, we first present a novel XML node categorization model. The XML node categorization helps us exploit the XML schema, embedded in the XML data, to identify relevant data keywords and XML schema elements in the context of a user query. We also present the definitions of LCE nodes and *DI*, GKS system architecture and the indexes maintained by GKS.

2.1 Preliminaries

An XML document is a rooted tree T as shown in Figure 2(a). Nodes in the tree are labeled with Dewey id [1]. Dewey id is a unique id assigned to a node that describes its position in the tree T . A node with Dewey id 0.2.3 is the fourth child of its parent node 0.2. n_{id} represents an XML node with Dewey id id . $v \prec_a u$ denotes that node v is an ancestor of node u . $v \prec_a u$ denote that $v \prec_a u$ or $v=u$. U represent a set of XML nodes (or keywords) in XML tree T . $v \prec_{lca} U$ denotes that v is the lowest common ancestor of nodes in set U . For a text keyword or XML node k , $k \in v$ denotes that k occurs in the sub-tree rooted at XML node v and $k \notin v$ denotes that k does not occur in v 's sub-tree. u^* denote that one or more siblings of node u exist in tree T with same XML element label. $v \prec_e u$ denotes that v is an entity node w.r.t. u (Def. 2.1.3) and $u \in v$ or $v=u$. $v \prec_{lce} u$ denotes that XML node v is the lowest common entity node (LCE) w.r.t. node u (Def. 2.2.1) and $u \in v$ or $v=u$.

2.2 Node Definitions

We divide the XML nodes in the following categories, based on the structure of their sub-trees in T .

2.1.1. Attribute Node (AN): A node which contains only one child that is its value. For instance, in Figure 2(a) node $\langle Name \rangle (n_{0.1.0})$ is an attribute node. Attribute nodes are also represented as ‘text nodes’ in XML data. The parent node of an attribute node is

considered the lowest ancestor for keyword(s) in its value (and not the attribute node itself). Thus, ancestor of ‘Databases’ is node $n_{0.1}$.

2.1.2. Repeating Node (RN): Let $v \prec_{lca} u^*$, i.e., v is the lowest common ancestor of multiple instances of node u . u is called the repeating node w.r.t. node v . For instance, in Figure 2(a), nodes with label <Student> are repeating nodes w.r.t. <Students>. The repeating nodes most likely correspond to a physical world object which could be a concrete or an abstract object [3]. A node that directly contains its value *and* also has siblings with the same XML tag is considered a repeating node (and not an attribute node), i.e., <Student> nodes in Figure 2(a).

2.1.3. Entity Node (EN): Let v be an XML node in XML tree T such that $v \prec_{lca} (u^*, A) \mid \forall a \in A, a \notin u^*$. v is an entity node. A is a set of attribute nodes. An attribute node $a \in A$ does not occur in any repeating node u , i.e., a does not have u in its XPath from root.

An *entity node* v is a lowest common ancestor of repeating nodes u and one or more attribute nodes ($|A| \geq 1$). In Figure 2(a) <Area> ($n_{0.1}$) is an *entity node*; it is the lowest common ancestor of attribute node <Name> ($n_{0.1.0}$) and repeating nodes <Course> ($n_{0.1.1.x}$). <Course> nodes are not the direct children of $n_{0.1}$ (Attribute nodes and Repeating nodes can be indirect children of *entity node*). Similarly, <Course> nodes ($n_{0.1.1.0}$, $n_{0.1.1.1}$, $n_{0.1.1.2}$, ...) are the entity nodes.

2.1.4. Connecting Node (CN): Nodes which are in none of the above categories. In Figure 2(a), <Courses> ($n_{0.1.1}$) is a connecting node.

Table 2: Notation

s	Minimum number of keywords from a query that must appear in the sub-tree of a XML node.
$R_Q(s)$	Set of XML nodes for a given s , returned by GKS in response of query Q
$R(e)$	For an LCE node $e \in R_Q(s)$, $R(e)$ is a subset of text keywords, extracted from attribute nodes of e .
S_Q^w	Weighted set of text keywords, identified from the LCE nodes in set $R_Q(s)$.
$\prod_{r=R_Q}$	Set of XML nodes, after recursively applying the GKS algorithm r times over the query results $R_Q(s)$.

XML documents follow pre-order arrival of nodes. Hence, different node types are identified in a single pass over the data. GKS does not need the XML schema in order to categorize nodes. XML nodes are categorized at the instance level. This information is stored in an index (Section 2.4). Hence, each node is categorized based on the structure of its sub-tree. For example, all the instances of <Course> node in Figure 2(a) are *entity nodes* (Def. 2.1.3). However, if a <Course> node had just one student in its sub-tree, that instance would have been stored as ‘Connecting node’ in the index. GKS can be easily extended to take into account the XML schema to categorize the nodes. This is part of our future work.

The node categories described above extend the node categorization model in [3]. It is argued in [3] that in the hierarchical structure of XML data, repeating nodes (Def. 2.1.2) capture the concept of physical world object. The physical object could be a concrete or an abstract object. In normalized XML data, attributes of an XML node that contains repeating nodes in its sub-tree, represent the information that is common to these repeating nodes [14]. The fundamental design principle underlying the normalized XML schema is, the attribute nodes of an XML node define the context of the repeating nodes in its sub-tree through their values. In GKS node categorization model, such XML nodes are termed entity nodes (Def. 2.1.3). As shown in the experiment in Section 7.2, we count the total number of XML nodes and XML

nodes that were labeled as entity nodes, attribute nodes and repeating nodes, respectively by GKS for many standard XML data repositories. The result shows that the real world data repositories are normalized. The node categories described above naturally capture the normalized XML data.

A node can be an *entity node* and at the same time a *repeating node* for another *entity node* higher up in the hierarchy. For instance, in Figure 2(a), <Course> nodes are both entity nodes as well as repeating node within the sub-tree of node <Area> ($n_{0.1}$). Let Q be a keyword query, $|Q| \geq s$, and $Q' \subseteq Q$; $|Q'| \geq s$. Let LCA node u for Q' is not an *entity node* and v is the lowest ancestor of node u such that $v \prec_e u$. Hence, node u can either be a connecting node or a repeating node w.r.t. v . Since u does not have the attribute nodes, as it is not an *entity node*, the context of the node u is most specifically defined by the attribute nodes of node v . In Figure 2(a), attribute <Course: Name: Data Mining> defines the context that <student> nodes in its sub-tree are registered in this course.

For a given keyword query, the closer the entity node is to the query keywords in its sub-tree, the more specific the context would be for those keywords. As we move up in the hierarchy, the context of the corresponding sub-tree becomes more general. In Figure 2(a), <Dept> node and <Course> node both are entity nodes and both contain the query keywords for a query $Q = \{‘Karen’, ‘Mike’\}$. However, the context of entity node <Dept> is much more general compared to more specific context of the node <Course>. Hence, to find the more meaningful response for a given query, we discover the entity node closest to the query keywords or Least Common Entity (LCE). LCE is formally defined below.

Let S_e be a set of all the *entity nodes* in the sub-tree rooted at an *entity node* e_c , i.e., $e_c \prec_a e; \forall e \in S_e$. Let Q be a keyword query, $Q = \{k_1, \dots, k_n\}$.

Def 2.2.1 LCE Nodes: An *entity node* e_c is an LCE node for query Q if $\exists k \in Q \mid k \in e_c \wedge \forall e \in S_e, k \notin e$.

Hence, for an *entity node* e_c to be LCE node for a given query Q , there exists at least one keyword $k \in Q$ in the sub-tree of e_c , which is *not* contained in any other *entity node* e such that $e_c \prec_a e$.

Keyword k is called an independent witness for LCE node e_c . Similar to an SLCA node, an LCE node also needs at least one independent witness.

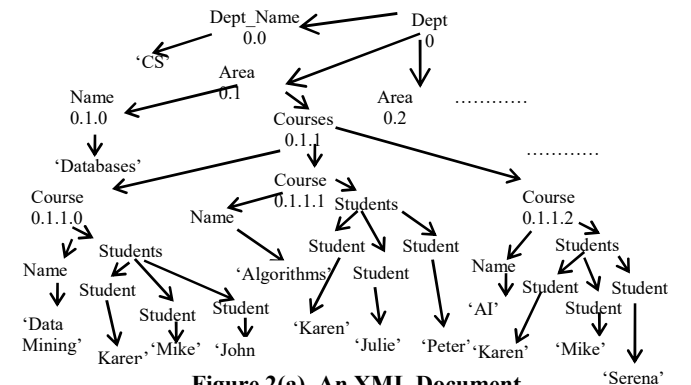

Figure 2(a). An XML Document

Lemma 1: Let $v \prec_a u$ denote a relationship that $v \prec_a u$ or $v = u$. Let u be an XML node that is an LCA node for a set of keywords $Q_s \subseteq Q$, $|Q_s| \geq s$. Let v be an LCE node for keywords in Q_s . $v \prec_a u$

Proof: Obvious. \square

For a given user query Q , GKS returns a set of XML nodes $R_Q(s)$ such that for each node $u \in R_Q(s)$, u contains at least s keywords from query Q .

Lemma 2: For a keyword query Q and integers s_1 and s_2 , $|Q| \geq s_1 > s_2$, $|R_Q(s_1)| \leq |R_Q(s_2)|$.

Proof: Since $s_1 > s_2$, $\forall v \in R_Q(s_1), \exists u \in R_Q(s_2) \mid v \prec_a u$. However, $\forall u \in R_Q(s_2)$ there can be at most one $v \in R_Q(s_1) \mid v \prec_{ice} u$. Thus, for $\forall v, v \in R_Q(s_1)$ there exist a corresponding node in $R_Q(s_2)$ but vice versa is not true. Thus, $|R_Q(s_1)| \leq |R_Q(s_2)|$. \square

Example 3: Let there be a user query $Q_4 = \{\text{student, karen, mike, john, harry}\}$, $s=2$. The intent of the query is to find the information about these students. For the data shown in Figure 2(a), 3 courses contain the names of at least one of these students. The GKS response constitutes the XML nodes as shown in Figure 2(b). The XML nodes are LCE nodes since they are the lowest entity nodes, w.r.t. query keywords. Attribute nodes of respective entity nodes exposes the context, i.e., name of the respective courses students are enrolled in. The XML nodes are ranked (cf. Section 5).

As one can see, the user query in Example 3 is ‘imperfect’. To construct a ‘perfect’ query, for a LCA based technique, user needs to be aware which students are enrolled in same courses. User still has to run multiple queries to get the complete response. GKS returns the relevant and meaningful information in the context of this ‘imperfect’ query. We further enhance a user’s capability to refine an ‘imperfect’ query by exposing the deeper analytical insights in the query response as explained in the next section.

2.3 Deeper Analytical Insights (DI)

For the query in Example 3, let’s say user runs a ‘perfect’ query $Q_5 = \{\text{student, karen, mike, john}\}$. The response of a LCA based technique [2][5] will be XML sub-tree rooted at node $n_{0.1.1.0.1}$ <Students> node. Even though the query is perfect, the response still does not yield any meaningful information. On the other hand, GKS response is node $n_{0.1.1.0}$ for $s=|Q|$ ($n_{0.1.1.0}$ is an LCE node for Q_5) with the aid of its node categorization model. Thus, GKS response exposes the information that the students are registered in ‘Data Mining’ course. This information, <Course: Name: ‘Data Mining’>, is called *deeper analytical insights* or *DI*. *DI* enables users to navigate the XML data by exposing relevant schema and the data elements that help users not only understand the query response but also help refine their queries.

Figure 2(b). Response of the GKS System for Q_4

To discover *DI*, for a user query Q and s , GKS prepares a set of keywords S_Q^w from nodes in set $R_Q(s)$ as follows: For each node $u \in R_Q(s)$, if u is an LCE node, GKS extracts the text keywords from its attribute nodes and put them in set S_Q^w . For instance, for the query in Example 3, entity nodes $n_{0.1.1.0}$, $n_{0.1.1.1}$ and $n_{0.1.1.2}$ are the LCE nodes in the set $R_Q(s)$ (Figure 2(b)). Each of the entity nodes has an attribute node <Name: Data Mining>, <Name: AI> and <Name: Algorithms>. The set S_Q^w will contain keywords {“Data Mining”, “AI”, “Algorithm”}. $R(e)$ represents the set of attribute

nodes in the sub-tree of entity node e (see Table 2). Given a query response $R_Q(s)$, we prepare a set of keywords $S_Q^w = \{k_1 \dots k_n\}$ containing the text keywords embedded in the attribute nodes for each of the entity nodes in $R_Q(s)$.

Def 2.3.1 DI: Let $E_Q \subseteq R_Q(s)$ be the set of all LCE nodes in GKS response for keyword query Q and let $S_Q^w = \bigcup R(e) \mid e \in E_Q$.

$$DI \subseteq S_Q^w \mid \forall k \in DI; k \notin Q.$$

For a keyword k in DI , let e be its corresponding LCE node. For the keyword k , we also associate the XML elements in the path from node e till keyword k . The keywords and the associated XML elements with each keyword together form the *DI*.

DI can also be discovered recursively for a user query as described below. We use only set $R_Q(s)$ and not E_Q since context is clear.

i) GKS parses the LCE nodes in set $R_Q(s)$, for a given keyword query Q and prepares a weighted set of keywords S_Q^w by identifying a subset of text keywords in each of the LCE nodes (Section 6.2).

ii) *Top-m* most weighted keywords in the set S_Q^w are fed to GKS as a query. GKS identifies a set of XML nodes w.r.t. these keywords from set S_Q^w . This set of XML nodes is denoted as $\prod_1 R_Q(s)$. Set

$$\prod_0 R_Q (\prod_0 S_Q^w) \text{ is denoted by just } R_Q(s) (S_Q^w).$$

The above steps can be applied recursively -- $\prod_r R_Q(s)$ represents the set of LCE nodes after r^{th} recursion.

iii) GKS prepares the set of keywords $\prod_r S_Q^w$ from the nodes in $\prod_r R_Q(s)$. DI_r is extracted from $\prod_r S_Q^w$; $r \geq 0$.

DI can be discovered recursively for a user query Q by extracting a ranked list of most relevant keywords and their semantics from $\prod_r S_Q^w$ at each step i of recursion. In summary, *DI* is discovered 1) with the aid of GKS node categorization model; and 2) *because* GKS does not impose the LCA constraints and thus retrieves all the relevant XML nodes in the query context. These XML nodes help discover meaningful *DI*.

2.4 GKS Architecture and Indexes

In Figure 3, we depict the architecture of GKS. The GKS takes as input XML data and prepares an index on it. The XML data could be spread over multiple files. For a user query Q , GKS produces a) ranked search results on the data; b) deeper analytical insights (*DI*) by analyzing search results. GKS contains three modules; i) Indexing Engine; ii) Search Engine; iii) Search Analysis Engine.

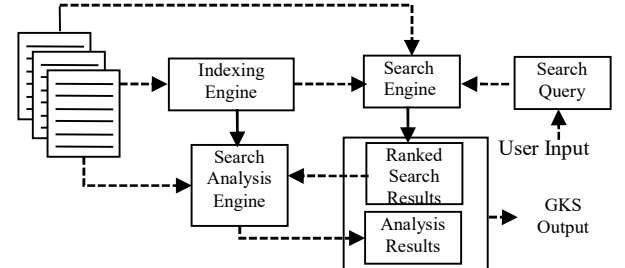

Figure 3. Architectural of the GKS System

For a given XML data repository, we first prepare an index on it. This is a onetime activity. We keep the following indexes:

Inverted Index for text keywords: For each unique text keyword that appears in the XML document repository, we keep an inverted index list. If text appearing under a ‘text node’ comprises multiple

keywords, a separate index entry is created for each of the keywords after stop words removal and stemming. A partial inverted index for document in Figure 2(a) is shown in Table 3. The inverted index list for a keyword k_i contains the Dewey id of all the nodes which contain that keyword. Dewey id for each node has been appended with the document id ' d_{id} '. Thus, GKS search is seamlessly expanded over multiple documents by prefixing Dewey ids with corresponding document id. For a keyword k_i present in the XML document repository, S_i denotes its inverted index list.

Hash tables: We keep two hash tables corresponding to XML elements. Hash table 1, called '*entityHash*', keeps the Dewey id of entity nodes. Hash table 2, called '*elementHash*', keeps the Dewey ids of repeating nodes and connecting nodes. Both hash tables also store the number of direct children each node has. This information is used while computing the rank of a node (Section 5). If a XML element is both a 'repeating node' and an 'entity node', its entry is present in both the hash tables.

Since XML nodes arrive *pre-order* (an ancestor of an XML node always appears before it), the hash tables and the inverted index are created in a single pass over XML data.

Table 3. Partial inverted index for XML document in Fig 2(a).

Karen	$d_{id}.0.1.1.0.1.0$	$d_{id}.0.1.1.2.1.0$
Mike	$d_{id}.0.1.1.0.2.0$	$d_{id}.0.1.1.2.2.0$

We provide two functions: i) *isEntity* (Deweyid); ii) *isElement* (Deweyid). Both the functions return the number of direct children for a given node has if true, null otherwise.

3. EXISTING WORK in the GKS CONTEXT

A large body of work exists to understand the user's intent for a keyword query over XML data. The work related to GKS can be divided into 3 categories: 1) Identifying meaningful return nodes for a keyword query, 2) Result type deduction techniques and 3) Ranking the XML nodes retrieved in response to a user query.

Identifying meaningful return nodes: Users present their keyword query and the underlying algorithm interprets the user's intent and tries to identify the return nodes accordingly [2][3][5][6]. The existing approaches for identifying most relevant return nodes are based on first discovering SLCA nodes [13]. Different heuristics are applied on the set of SLCA nodes to identify meaningful return nodes. In XSeek [3], authors propose a technique that first finds the SLCA nodes for a given keyword query. The keywords in the query are understood as the 'where' clause whereas 'return' nodes are inferred based on the semantics of 'query keywords'. MaxMatch [11] and RTF [12] are SLCA based approaches to identify meaningful return nodes. In [11], irrelevant match results are filtered from each SLCA node. In [12], authors propose an improved algorithm to address *redundancy* and *false positive* problems of [11]. In all the approaches above, a set of SLCA nodes is identified for given keyword query. In [10] authors address the problem due to imprecise XPath queries.

Deducing result types: Deducing return node types is also an important goal for GKS since for most keyword queries, users target certain node types. However, due to lack of knowledge about the distribution of keywords in the document, different semantic meaning of same keywords or due to lack of familiarity with the document schema, the query may not be semantically 'perfect'. In [15][19], it is assumed that the keyword query is semantically correct and certain node types are the target nodes for a given query. XReal [9] and XBridge [4] address the problem of deducing the return nodes types. In [9] the authors count the confidence level to deduce the result node types. In [4] authors highlight the fact that keywords may exist in different context. XBridge automatically

predicts the intended result types for XML keyword queries by considering the value and structural distributions of the data. The more generic solution to this problem is to enable users to further refine their queries. GKS approach is a step in that direction.

Ranking the XML nodes: The XML ranking techniques are divided into IR [9][8] based methods and relevance score based [15][7] methods. XRank [7], XSearch [8] are techniques to rank the keyword query search results based on LCA nodes. XRank takes into account the keyword proximity in the XML nodes whereas XSearch computes the node rank based on TF-IDF based method. The basic differences between these methods and GKS technique is: In existing XML ranking methods, each of the XML nodes that is ranked contain a fixed set of all query keywords. XML nodes in GKS response contain varying number of query keywords. We have outlined the issue arising due to this difference in Section 5 when we present GKS ranking methodology.

4. SEARCHING GKS NODES

The basic difference between the LCA based search and GKS-Search is: GKS has exponential search space compared to LCA

based techniques. For query Q ($|Q|=n$), a total of $(2^n - \sum_{i=1}^s \binom{n}{i-1})$

sub-sets, of size at least s , can be formed; $s \leq n$. To identify GKS nodes, a naïve approach would be to create all the keyword subsets (of size $\geq s$) for query Q , and for each of these keyword subsets, identify the LCA nodes. Together, all the LCA nodes thus discovered can be used to produce the GKS response. However, this approach results in an exponential number of sub-queries.

Lemma 3: For a given query Q , $|Q|=n$, $s \leq \lfloor n/2 \rfloor$; GKS has exponential search space w.r.t. an LCA based techniques.

Proof: For a given query Q , $|Q|=n$, a total of $U = 2^n - \sum_{i=1}^s \binom{n}{i-1}$ sub-

sets can be formed such that each set is of size at least s . Now,

$$\sum_{i=1}^n \binom{n}{i-1} = 2^n - 1 \Rightarrow \sum_{i=1}^n \binom{n}{i-1} \leq 2^n \text{ since } \binom{n}{i} = \binom{n}{n-i}. \quad \text{Hence,}$$

$$\sum_{i=1}^{\lfloor n/2 \rfloor} \binom{n}{i-1} \leq 2^{n/2}; \quad \text{Therefore } \sum_{i=1}^s \binom{n}{i-1} \leq 2^{n/2}; s \leq \lfloor n/2 \rfloor$$

Since, $U = 2^n - \sum_{i=1}^s \binom{n}{i-1} \Rightarrow U \geq 2^{n-1}$. Therefore, an exponential

number of sub-sets are formed when $s \leq \lfloor n/2 \rfloor$ with each sub-set leads to one keyword query for an LCA based techniques. \square

Lemma 3 shows GKS has exponential search space w.r.t. LCA based techniques. Further, the naïve approach does not discover the LCE nodes, in absence of GKS node categorization model, which allow GKS to expose *DI* in the context of the user query. Hence, LCA techniques cannot be applied as is for GKS-Search. In this section, we present an efficient method to find relevant XML nodes for GKS-Search. We call them GKS nodes. A subset of GKS nodes can be LCE nodes. We also present the correctness analysis and time complexity analysis of our method.

4.1 Efficient Method to Search GKS nodes

For the query keywords $k_i \in Q$, we first merge their respective inverted index lists such that in the merged list, keywords follow their arrival order in the XML document. Since the Dewey ids of the XML nodes follow *pre-order* traversal, if the merged list is sorted on Dewey ids, we achieve such ordering. Let d be the depth of the XML tree T being queried. Depth of the tree T is defined as

the number of edges from the root of the tree to its deepest leaf. Let $|Q|=n$, i.e., n lists are merged. Let $|S_i|$ be the inverted index length for keyword $k_i \in Q$. Let S_L be the merged and sorted list. $|S_L| \leq$

$\sum_{i=1}^n |S_i|$. The time complexity to merge k sorted lists, of total length l , into a single sorted list in $O(l \log k)$. Since the inverted index list for each keyword is sorted on its Dewey id, therefore the n lists are merged in a single sorted list S_L in $O(d|S_L| \log n)$.

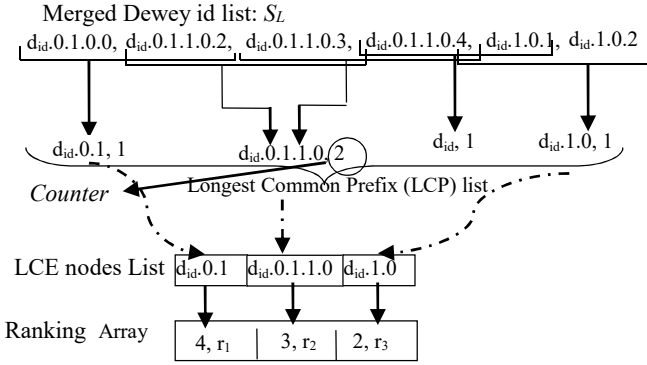

Figure 4. List of longest common prefixes for Dewey id blocks of size $s=2$

Generating list of candidate GKS Nodes: Our next objective is to generate the list of candidate GKS nodes that have $Q_s \subseteq Q$ keywords appearing in their subtree such that $|Q_s| \geq s$. Towards that end, in the merged list S_L , longest common prefix is identified for a continuous block of s entries, as shown in Figure 4 (in Figure 4, $s=2$). We traverse the list S_L from left to right. Since the list S_L is sorted, the Dewey ids of the nodes in a common sub-tree occur next to each other, with an ancestor node preceding its descendent. Therefore, in S_L , the longest common prefix of a block of s nodes will be the Dewey id of the common ancestor for the nodes in this block. There will be at most $(|S_L| - s)$ such prefixes.

The prefixes are put in Longest Common Prefix (LCP) list as shown in Figure 4. With each prefix entry in LCP list, we associate a *counter* which is initialized to 1. If a prefix exists in the LCP list (i.e., more than s query keywords exist in its sub-tree), its counter is increased by 1. Since the block of s entries in the list S_L slides to the right by 1 at a time, the *counter* can increase by only 1 at a time.

Figure 5. Traversal of list S_L

The objective of GKS is to collect s unique keywords from query Q in the sub-tree of a GKS node. However, it is possible that not all s keywords in the continuous block of length s are unique. Therefore, we first collect a block such that there exist s unique keywords in it, as shown in Figure 5. For a block of length s , let l and r represent the left and right end of the block respectively. Function $sU(l, r, s)$ returns true if there are s unique keywords in the range of l to r (with the aid of hash tables, Section 2.4). Until $sU(\cdot)$ is true, we just move r to the right, keeping l fixed. When $sU(\cdot)$ is true, range l and r represent a block containing s unique keywords. Once the correct block is found, the longest common prefix of the block is added to the LCP list.

We generate the list of LCE nodes from LCP list. For each of the entries in LCP list, we check the *entityHash*, prepared at the time of parsing XML document repository. For each entry in the LCP list, we check if it is an entity node or any of its ancestors is an entity node (using *Dewey id* we can get the Dewey ids of all if its ancestors). If the node (or any of its ancestors) is found to be entity node, we add the corresponding Dewey id into a LCE node list. We also maintain a ‘Ranking array’ which has an entry corresponding to each GKS node. Each entry in the ranking array maintains two scores as shown in Figure 4. One is the number of keywords $k_i \in Q$ appearing in GKS node sub-tree and the other is its ranking score (computation of the ranking score is described in Section 5). The number of query keywords in the GKS sub-tree is $(s + counter - 1)$.

Algorithm GKSNodes (Set Q) // Q contains query keywords

Merge the sorted inverted index list S_i for $\forall k_i \in Q$ into list S_L

// Find Longest Common Prefix (LCP) list

$l=0; r=s-1;$

Traverse S_L from left to right

while ($!sU(l, r, s)$) $r++;$ // Identify block of s unique entries

Find longest common prefix (LCP) of s unique entries;

Add LCP to LCP list;

if ($sU(l, r, s)$) $r++; l++;$

for each entry e_n in LCP list // Find LCE node list from LCP list

$e_c = \text{null};$

if ($isEntity(e_n) > 0$)

Add e_n to LCE node list; $e_c = e_n$; Remove e_n from LCP list;

else if (any ancestor $e \prec_a e_n$ & $isEntity(e) & e \notin \text{LCE node list}$)

Add e to LCE node list; $e_c = e$; Remove e_n from LCP list;

if ($e_c \neq \text{null}$)

for ($\forall e \prec_a e_c$)

if ($isEntity(e) > 0$ & $e \in \text{LCE node list}$)

Update LCE node (e);

Rank nodes in LCE/LCP node lists;

return ranked LCE/LCP lists;

Figure 6: GKS algorithm for finding XML nodes

Example 4: In Figure 4, $d_{id}.0.1$ is the longest common prefix (LCP) of block of first s nodes. Its entry is created in the LCP list with *counter* set to 1. In Figure 4, node $d_{id}.0.1$ is found to be entity node. An entry for it is created in LCE node list with keyword counter set to $(s + counter - 1) = 2$. Similarly, the next entry in LCP list $d_{id}.0.1.1.0$ is initiated with counter set to 1. While checking its ancestors, node $d_{id}.0.1$ is found to be an entity node. Since $d_{id}.0.1$ already exist in the LCE node list, its entry (i.e., number of keywords in its sub-tree) is updated to 3 (since node $d_{id}.0.1.1.0$ appears in its sub-tree). Finally, the keyword count of node $d_{id}.0.1$ is incremented to 4 and for node $d_{id}.0.1.1.0$ to 3 (due to next keyword with Dewey id $d_{id}.0.1.1.0.4$). Once the LCE nodes list is computed along with the number of keywords in its sub-tree, we compute a ranking score r_i for each LCE node, as explained in Section 5. It is also possible that for some node in LCP list, no corresponding LCE node is found.

4.2 Correctness and Time Complexity

In this section, we present the analysis of our method and prove the correctness of our methodology to discover the LCE nodes.

For LCE node e , there must exist at least one keyword $k \in Q$ that is not contained in any other entity node within its sub-tree (Def. 2.2.1). k is called the independent witness of node e . Correctness is defined as discovering LCE nodes according to Def. 2.2.1. We now prove the correctness of our methodology to discover LCE nodes. To discover LCE nodes, LCP list is traversed from left to right. Let left and right pointers l and r of the current block under consideration are at position p_1 and p_2 respectively in list S_L when entity node e is first time being added to the LCE list.

Lemma 4: For entity node e , just being added to the LCE list, *only* Dewey id of the keyword at position p_1 or at position p_2 can be the smallest Dewey id which is independent witness for node e .

Proof: Omitted. \square

Let k be the independent witness for node e with smallest Dewey id. We associate the Deweyid of keyword, k , with node e . Let e_n be the LCE node added immediately after node e in the LCE list. If $e \prec_a e_n$ and $e_n \prec_a k$, the entity node e is removed from the LCE list. The reason is: k is the earliest keyword in document order which was an independent witness for node e at the time of its addition to LCE list. Since k itself appears in the sub-tree of its descendent entity node e_n , e is left with no independent witness and hence removed from the LCE list. Note, e can come back in LCE list if any other keyword is found to be an independent witness for it later in list S_L . Any entity node e that survives has at least one independent witness. In Figure 4, entry $d_{id}.0.1$ survives in LCE node list at the time of addition of $d_{id}.0.1.1.0$ since it has an independent witness. If any entity node e , $e \prec_a e_n$, of a newly added entity node e_n remained in the LCE list, we update its ranking array.

Lemma 5: For each LCE node e that survives in LCE node list, there exists a keyword k that is an independent witness of e .

Claim 1: Let e be a lowest common entity node for a block of s keywords. We claim that at least one of the keywords in the block is an independent witness for node e .

Proof: Proof is by contradiction. Suppose no keyword in the block of s keywords is an independent witness for LCE node e . Hence there must exist another LCE node in the sub-tree of e , which contains all the keywords from the block. Hence node e is not the *lowest* common entity node, contradicting the initial assumption. \square

Claim 2: Any ancestor entity node e , of entity node e_n , which is *not* already present in the LCE node list at the time of addition of node e_n in the LCE list, is *not* the LCE node.

Proof: As entity node e , $e \prec_a e_n$, is not in LCE list, therefore it has no independent witness keyword at the time of addition of e_n . Since e_n is the lowest entity node for the current block of keywords, e cannot be an LCE node. \square

Thus, LCE node e that survives in LCE node list, there exists a keyword that is an independent witness. When the traversal of LCP list is complete, LCE list contains only true LCE nodes (Def. 2.2.1).

Time complexity to generate the longest common prefix list is $O(d \cdot |S_L|)$ due to Lemma 6 below (the worst case time complexity could be $s \cdot d \cdot |S_L|$ where s is a small constant). Since the Dewey ids are sorted, we just need to find the longest common prefix of first and last Dewey id in the block of s Dewey ids. There are $O(|S_L|)$ entries in longest common prefix list and depth of the document is d . Hence, time complexity to generate LCE nodes list is $O(d \cdot |S_L|)$.

Lemma 6: For lexically sorted block of s strings, the common prefix of first and last string is the longest common prefix for the strings in the block. \square

As the time complexity to generate merged Dewey id list is $O(d \cdot |S_L| \cdot \log n)$, total time complexity to generate LCE node list, along with its ranking score list is $O(d \cdot |S_L| \cdot (\log n))$. Therefore, we efficiently identify LCE nodes in a single pass.

For the LCA based search, the time complexity of the state of the art algorithm to find LCA nodes for query Q , $|Q|=n$, is $O(d \cdot n \cdot |S_{min}| \cdot \log |S_{max}|)$ where $|S_{min}|(|S_{max}|)$ is the length of the shortest (longest) inverted index list consisting the DeweyId of the keyword in query Q [6][16]. We see that the time complexity of our algorithm to find the GKS nodes is only marginally worse than the

time complexity to find LCA nodes, even though the search space for GKS is exponential compared to LCA nodes.

Nodes in Longest Common Prefix (LCP) list contain at least s keywords in their sub-tree. For each node u in LCP list we keep a mapping with its associated LCE node v in LCE list, $v \prec_a u$. There may exist some nodes in LCP list such that no corresponding entity node is found for them due to the structure of the XML data.

The XML nodes in LCE list along with those nodes in LCP list for which *no* corresponding LCE node exist together constitute the GKS response $R_Q(s)$. These nodes are ranked with the aid of ranking function presented in the next section.

5. RANKING

Node ranks help GKS construct a more meaningful response. Number of GKS nodes can be large and the response may comprise a variety of XML node types. The relevance of these nodes varies in the context of a given query. For LCA based techniques, each LCA node is the common ancestor of *all* the keywords in query Q .

Due to the basic differences between GKS and LCA based search, existing ranking algorithms [8][15] are insufficient for GKS. Existing ranking methods work by using aggregated statistical information for entire XML repository. For a fixed set of keywords, nodes are ranked based on statistical relevance of a query keyword in the context of a given XML node. For GKS, any node containing a subset of keywords belonging to query (of size $\geq s$) is the node of our interest. Further, GKS response may contain a variety of differently structured XML nodes. Therefore, any statistical method is insufficient to compare the relevance of one XML node w.r.t. other due to the structural difference in their sub-trees.

Therefore, we introduce a novel ranking function that computes the rank of each XML node in $R_Q(s)$ for query Q based on i) the number of keywords from Q appearing in its sub-tree; and ii) the structure of the sub-tree rooted at that node.

5.1 Ranking Methodology

We use a potential flow model to compute the rank of the XML nodes in $R_Q(s)$. Potential of a node is like the amount of water present in a reservoir which flows in a network of pipes coming out from it. The potential flow model automatically incorporates the structure of the sub-tree rooted at an XML node.

We assign an initial potential, $P|e$ to each node $e \in R_Q(s)$. $P|e$, for node e is equal to the number of unique query keywords $k \in Q_s$, $Q_s \subseteq Q$, present in its sub-tree.

$$P|e = |Q_s|; Q_s \subseteq Q; Q = \{k_1, \dots, k_n\}$$

$P|e$ just accounts for the presence of a keyword $k \in Q$ in the sub-tree of node e . If the keyword k is present multiple times in node e , only its highest occurrence in its sub-tree is considered. This highest occurrence of a query keyword in the sub-tree is termed *terminal point*. If a keyword k is present multiple times at the highest level, *each* of its occurrences is considered a terminal point. For example, if a keyword $k \in Q$ is a repeating XML element name in the sub-tree of an LCE node, each of its occurrence will be considered as a terminal point (assuming that is the highest level at which keyword k occurs). Hence, for a user query $Q = \{k_1 \dots k_n\}$, each candidate XML node has a starting potential. As shown in Figure 7, for node e_1 , the highest occurrence of keywords k_1, k_2, k_3 are *terminal points*.

The rank of a node $e \in R_Q$ is computed as follows: The potential of a node e is equally divided into each of its child nodes. For a node

e with potential ($P|e$), with m children, each of its child nodes will receive ($P|e$)/ m potential, where m is the number of direct child the node e has. The rank of the node is sum of the total potential received by each of the terminal points.

Let $i \rightarrow k$ denotes the relationship that node i is parent of node k . The rank of an entity node e is computed as follows:

$$Rank_e = \sum_{k \in Q} \frac{P_i}{m_i} | i \rightarrow k$$

where k is a terminal point in the sub-tree of node e , p_i is the potential received by its parent node i and m_i is the total number of direct children node i has. The potential received at terminal points depends on the structure of the sub-tree rooted at the XML nodes.

Intuitively, it implies that the number of distinct query keywords in its sub-tree and the structure of its sub-tree determine the rank of an XML node. Each LCE node is ranked independently, irrespective of its relative depth w.r.t. document root.

Figure 7. LCE nodes containing keywords in set $R_Q(s)$

Example 5: We illustrate the computation of XML nodes rank with the example XML document shown in Figure 1. For query $Q_3 = \{a, b, c, d\}$, GKS returned 3 XML nodes x_2, x_3 and x_4 . The initial potential of node x_2 is $P|x_2=3$. The rank of node x_2 is the potential received by the terminal nodes in its sub-tree, i.e., nodes a_2, b_1, c_1 .

The rank of node $x_2 = \sum_{k \in Q} P|x_2/n = 3 \times 3/3 = 3$. Similarly, for

node x_3 , the initial potential $P|x_3$ is 3. The three terminal nodes are nodes a_3, b_3, d_3 . Each of the three children of node x_3 received $1/3^{rd}$ of the initial potential. The potential received by x_4 is further divided equally into its two children. Therefore, the total potential received by the terminal nodes, i.e., the rank of node x_3 is, $2 \times 3/3 + 3/3 \times 1/2 = 2.5$. Similarly, the rank of node x_4 is 2. Hence, GKS ranking methodology ranks the nodes as $x_2 > x_3 > x_4$.

6. SEARCH RESULTS ANALYSIS

GKS enables the users to refine their queries. The user query Q can be refined by either removing or adding the most relevant keywords to Q , in the context of the query. We now describe how GKS aids the users to refine their query by analyzing the search response.

6.1 Query Refinement

Let us consider the Example 1. For query $Q_3 = \{a, b, c, d\}$, the response of GKS comprised nodes, x_2, x_3 and x_4 . GKS ranks the nodes such that most relevant nodes are ranked higher. The two top ranked nodes are x_2 containing keywords $\{a, b, c\}$ followed by x_3 containing keywords $\{a, b, d\}$. With this information, the user is exposed to the fact that there is no XML node that contains all the query keywords and that the distribution of the query keywords in the document is as shown in the query results. With this insight, users can refine their queries. In the example above, user can refine the query Q_3 to $\{a, b, c\}$ or $\{a, b, d\}$ given the GKS response.

Therefore, for a user query Q , the query can be refined seamlessly to one or more sub-queries Q_s with the aid of the GKS results. As one can see, for LCA based techniques [2][5][17], such refinement of the query Q is non-trivial as multiple sub-queries of Q needs to be run to collect the complete response.

6.2 DI-Discovery from the LCE Nodes

GKS enables the discovery of DI from the XML data in the context of the user query which can be used to refine the user query. For a given query, the attribute nodes of a LCE node expose the context for the keywords appearing in its sub-tree and are regarded as the relevant DI (Def 2.3.1).

A natural way to discover DI is by identifying *top-m* most popular attribute keywords in the LCE nodes present in the query response, i.e., identifying keywords that appear in maximum number of attribute nodes (m is tunable). At the same time, the DI must be relevant for most of the query keywords. However, these two goals may translate into two different set of top DI keywords. In response of the query in Example 2 (Section 1.2), the most popular keyword is found to be <booktitle: ICPP>. However, the keyword became most popular due to presence of keyword 'Prithviraj Banerjee'. He is the only author who had published articles in this journal but total number of articles by him alone in this journal made it the most popular keyword in the query response. However, this keyword is not relevant for majority of the other query keywords. The keyword <journal: SIGMOD Record> is relevant for the largest sub-set of the query keywords (for remaining three authors) but it is not the most popular. Therefore, to identify most relevant keywords in the context of a query, we adopt the following approach.

Rank of a LCE node is the function of number of query keywords present in its sub-tree. Each attribute node is assigned a weight equal to the rank of its LCE node. Therefore, each keyword in set S^w_Q is assigned its attribute weight and we prepare a weighted set S^w_Q . Let $E_Q \subseteq R_Q(s)$ be a set of all the entity nodes in $R_Q(s)$.

$$S^w_Q = \{k : w | w = \sum_{e \in E_Q} Rank_e, e \in E_Q \wedge k \in attr(e) \wedge k \notin Q\}$$

Each element of set S^w_Q is a tuple $k : w$, where k is the attribute keyword. k is assigned a weight that is sum of the rank of all the LCE nodes in set E_Q that contain k . The *top-m* most weighted keywords constitute DI . If a keyword in the attribute node is part of the user query Q , it is not included in the set S^w_Q . We identify *top-m* elements in set S^w_Q , total time complexity to identify DI is $O(|S^w_Q| + m \cdot \log |S^w_Q|) = O(|S^w_Q|)$ as $|S^w_Q| \gg m$. Since $|S^w_Q| = O(|R_Q(s)|)$ and $|R_Q(s)| \leq S_L$, the time complexity to identify DI is better by a factor of $O(\log |Q|)$ compared to the time complexity to identify LCE nodes and DI discovery does not constraint the system. In Example 2, DI contained <year: 2001>, <booktitle: ICPP>, <author: Alok N Choudhary>, etc., as top DI keywords. Recursive DI can be discovered by preparing a keyword query using the text keywords identified from S^w_Q . The recursive DI may reveal deeper insights.

Therefore, a user query Q can be refined seamlessly to Q_s with the aid of DI . We see that with the aid of response produced by GKS and with the aid of DI , user queries can be refined by adding or removing the keywords from the initial keyword query.

7. EXPERIMENTS

We have built a prototype of GKS [20]. Observations in this section are based on experiments using this prototype over the XML data sets shown in Table 4 [21]. Shakespeare's plays are distributed over multiple files. The experiments were carried out on a Core2 Duo 2.1GHz, 4GB RAM machine running Windows 7 and Java. These data sets are used in many prior works [3][11][13][19]. The size of

Protein Sequence dataset is comparable to the biggest dataset used in a recent work [19]. Our DBLP dataset size is 100% bigger.

Our experiments are designed to assess 1) Performance of GKS; 2) Appropriateness of the node categorization model given the real world XML repositories; 3) Effectiveness of GKS in finding the relevant results for keyword queries and to rank them; 4) Ability of GKS in finding the relevant *DI*; 5) User feedback.

7.1 Performance of GKS

7.1.1 Size of Index

Creating the index is a onetime activity. The size of index and the time taken to prepare them are presented in Table 4. *Our technique is highly scalable as index preparation time increases linearly with the data size.* The number of entity nodes for different datasets varied from 535 for Mondial to 2.62M for DBLP.

Table 4. Index Size and Index Preparation Time

Data Set	Data Set Size	Index Size	XML Depth	Index Preparation Time
SIGMOD Records	483KB	416KB	6	0.15s
Mondial	1.7MB	1.45MB	5	0.28s
Plays	1.8MB	1.6MB	5	0.29s
TreeBank	82MB	79MB	36	19.3s
SwissProt	112MB	101MB	8	21.3s
Protein Sequence	683MB	612MB	7	108s
DBLP	1.45GB	1.13GB	6	238s

7.1.2 Response Time

In this experiment, we assess the response time (RT) of GKS for given user queries. We also validate GKS time complexity analysis to discover the XML nodes for the given queries. We give RT results for two datasets: i) NASA dataset containing astronomy data (24MB) and ii) SwissProt dataset containing protein sequence data (112MB). In our first experiment, the number of keywords for each query (n) was fixed at 8. However, the size of the merged Dewey id list (S_L) varied for each query. The average keyword depth d for the NASA dataset varied from 6.7–6.9 and from 3.1–3.5 for SwissProt dataset. Results are presented in Figure 8. As shown in Section 4.2, for given d and n , the RT increases linearly with S_L . Response time varies from 21.5ms to 139ms for different queries. Hence, the RT of GKS is only a few tens of ms, similar to LCA based algorithms on similar data.

Figure 8. Response Time Vs. Merged List Size

In Figure 9, we plot the RT for queries by varying the number of query response keywords n from 2 to 16. The query response time validates our analysis (cf. Section 4.2). The list size $|S_L|$ for query on SwissProt dataset with $n=16$ was 102,233. In Figure 9, for the NASA dataset, when n is increased from 8 to 16 for a query, the increase in RT was less than twice, as the length of the list $|S_L|$ increased only marginally and the change in RT is logarithmic in n .

For a query run on the DBLP dataset, the RT was found to be 2ms for $|S_L|=213$. Hence, *RT depends on the query, i.e., depth d , n and S_L ($O(d \cdot |S_L| \cdot \log n)$), and not on the size of the data being queried.*

Figure 9. Response time vs. keywords in query response (n)

7.1.3 Scalability

Figure 10. Response time for different dataset sizes

To assess the scalability of GKS, we replicated the Swiss Prot dataset to create three datasets of size 112MB, 225 MB and 336 MB. For same query, the number of LCE nodes scales linearly. In Figure 10, we plot our results. We can see that *query processing time is scaling linearly with data size, as expected.*

7.2 Validation of Node Categorization Model

In this experiment, we analyze the structure of the real world data repositories. XML nodes are placed in different categories as described in Section 2.2. In Table 5, we show the number of different XML element types belonging to different node categories for various XML repositories. As we see, the fraction of nodes labeled as Connecting Nodes (CN) varies from around 15% for InterPro to less than 3% for DBLP dataset. In DBLP/Sigmod Records some nodes with similar schema as that of *entity nodes* (EN) are marked as CN because of the presence of just a single author. We compared the results of our analysis with the ground truth, i.e., with XML schema. For Sigmod Records, two XML elements, <articles> and <authors>, were the connecting nodes as per the XML schema. The count of <authors> node, was 1504, and count of <articles> node was 67 (remaining 447 XML nodes were marked CN due to presence of <article> nodes with a single author). The results show *our node categorization model captures the structure of the real world data repositories very well.*

Table 5. Distribution of XML element

Data Sets	Count of AN	Count of EN	Count of RN	Count of CN	Total Nodes
Sigmod Record	10574	1022	3766	2018	15263
DBLP	27.58M	2.62M	10.56M	972367	39.52M
Mondial-3.0	7467	535	15074	663	22423
InterPro	515316	32614	1472021	303079	2088766
SwissProt	4044884	176128	1776676	187300	5166890

7.3 Finding and ranking the XML nodes

The purpose of this experiment is to assess the quality of GKS results. Therefore, some queries are designed for which SLCA

response is obviously inadequate (the response of an SLCA technique is either null or document root for these queries). For a few queries, SLCA returns meaningful response (QM1, QI1, QI2). Queries for different datasets are shown in Table 6. The number of keywords for the queries was varied from 2 to 8. We present the number of XML nodes retrieved by GKS and SLCA. We vary s , the minimum number of query keywords in the XML node subtree. s is set to be 1 and $|Q|/2$ respectively.

Table 6. Keyword queries run on different datasets

	$ Q $	SIGMOD Records
QS1	2	"Anthony I. Wasserman" "Lawrence A. Rowe"
QS2	4	"S. Jerrold Kaplan" "Robert P. Trueblood" "David J. DeWitt" "Randy H. Katz"
QS3	6	"Sakti P. Ghosh" "C. C. Lin" "Timos K. Sellis" "David A. Patterson" "Garth A. Gibson" "Randy H. Katz"
QS4	8	"Barbara T. Blaustein" "Umeshwar Dayal" "Alejandro P. Buchmann" "Upen S. Chakravarthy" "M. Hsu" "R. Ledin" "Dennis R. McCarthy" "Arnon Rosenthal"
	$ Q $	DBLP
QD1	2	"Dimitrios Georgakopoulos" "Joe D. Morrison"
QD2	4	"Peter Buneman" "Wenfei Fan" "Scott Weinstein" "Prithviraj Banerjee"
QD3	6	"E. F. Codd" "Mark F. Hornick" "Frank Manola" "Alejandro P. Buchmann" "Dimitrios Georgakopoulos" "Joe D. Morrison"
QD4	8	"E. F. Codd" "Kenneth L. Deckert" "Irving L. Traiger" "Vera Watson" "Jim Gray" "Chin-Liang Chang" "Nick Roussopoulos" "Jean-Marc Cadiou"
	$ Q $	Mondial
QM1	2	country Muslim
QM2	3	Laos country name
QM3	6	Polish Spanish German Luxembourg Bruges Catholic
QM4	8	Chinese Thai Muslim Buddhism Christianity Hinduism Orthodox Catholic
	$ Q $	InterPro
QI1	2	Kringle Domain
QI2	3	Publication 2002 Science

Results for different queries are shown in Table 7. We see a large number of XML nodes returned for the queries by GKS ($s=1$) compared to SLCA response. Thus, a lot of information that could be of the interest to the user for the given keyword query is not returned by LCA based techniques. Further, the number of XML nodes for ($s=|Q|/2$), is non-zero for all the queries. When we compared GKS with FSLCA [19], the top XML node for both QI1 and QI2 for GKS was present in FSLCA result set. For QM1, many XML nodes of FSLCA were among the top 10 nodes of GKS results. For QM2, no FSLCA node exists but GKS was able to find the XML nodes having subset of query keywords. There are no entity nodes which were relevant, i.e., contained at least s query keywords, but not identified by GKS. Therefore, *GKS is able to find valid response for the given user queries, without binding them to LCA framework, enhancing the users' ability to search the data.*

We next assess the ability of GKS to rank the discovered XML nodes. Since, the schema for DBLP and Sigmod Records is not very deep, the structure of all the XML nodes is similar for these two datasets. Hence, we adopt the measure that the higher the number of query keywords in an XML node sub-tree, the more relevant it is. Given this measure, we determine where GKS places the XML nodes with the highest number of query keywords in its ranking list.

Let L be a ranked list of XML nodes, in set $R_Q(s)$, returned by GKS for a query Q and for a given s , $|L| = p = |R_Q(s)|$. The nodes are numbered 1 to p according to their ranks. The XML nodes that contain the highest number of keywords from query Q in their subtree are called the true XML nodes. Let L' ($L' \subseteq L$) be a set of true

XML nodes. Let w be the lowest rank of a true XML node in the list of XML nodes L . To each true XML node, we assign a weight of $(w+1-i)$ where i is the rank of the true XML node in the list L . We compute the aggregated weight of true XML nodes as $w_a = \sum_{i \leq w} (w+1-i)$ for all the true XML nodes in the list L . The

total score is computed as $w_t = w(w+1)/2$. Finally, we compute a rank score as w_a/w_t . We penalize the rank score if a true XML node occurs lower in the list L . Score of 1 means that no true XML node is ranked lower than a XML node which is not in set L' . In Table 7, we show our results. The ranking score is computed for GKS response when $s=1$. We see that *the aggregate weight, i.e., rank score is very high for all the queries*. For every query, except QM3, the top-most result is always a true XML node. For QM3, it appeared at 3rd position.

Table 7. Comparison with SLCA and Rank Score

Query	#GKS, $s=1$	#GKS, $s= Q /2$	SLCA	Max keywords in a GKS node	Rank Score
QS1	8	NA	0	1	1
QS2	43	13	0	2	1
QS3	28	4	0	3	1
QS4	36	2	1	8	1
QD1	30	NA	1	2	1
QD2	234	10	0	3	0.72
QD3	190	7	0	5	1
QD4	267	4	0	6	1
QM1	230	NA	98	2	1
QM2	234	NA	1	2	1
QM3	37	4	0	3	0.17
QM4	116	3	0	6	1
QI1	8170	NA	8	2	0.893
QI2	2517	2517	281	3	1

In summary, we see that *GKS is able to retrieve and appropriately rank the relevant XML nodes, in the context of the user queries.*

7.4 Quality of DI Discovered by GKS

One of the most important attractions of GKS is its ability to discover *DI* in the data. In Table 8, we show the *DI* discovered for the queries in Table 6 for different values of s . This experiment highlights that the *DI* discovered by GKS is highly relevant for the given queries. For instance, for QD3, *DI* exposes the most relevant year (1999) and the most relevant 'booktitle' (ICCD). The keywords exposed as *DI* also help users understand GKS response since the *DI* keywords also represent the summary of the query response. For some queries, *DI* varies for different values of s .

Table 8. DI discovered for different queries

Query	$DI, s=1$	$DI, s= Q /2$
QS1	<title: Third-Generation Database System Manifesto >	<title: Cache Consistency and Concurrency Control>
QS2	<title: Chair's Message>	<title: Database Research Activities at the University of Wisconsin >
QS3	<title: article title>	<title: Implementation of a Prolog-INGRES Interface>
QS4	<title: article title>	NA
QD1	NA	<year:2000>, <journal:TCS>
QD2	<year: 2001>, <journal: SigmodRecords>	<year:1998>, <volume:2>
QD3	<year: 1999>, <booktitle: ICCD>	<journal: TCS>, <year: 2001>, <number: 1>
QD4	<year: 2001>, <journal: JACM>	<journal:IBM Research Report>, <year: 2001>

QM1	<country:f0_475>, <Year : 90>	NA
QM2	<Name : Zimbabwe>, <population growth : 1.41>	<Name:Zimbabwe>, <percentage : 100>
QM3	<country:f0_337>,<year: 90>	<country:f0_337>,<year:90>
QM4	<country:f0_663>, <percentage:100>	<country:f0_663>,<name:Brunei>
QI1	<author_list:Patthy L>, <taxon_data_name:Eukryot>	NA
QI2	<taxon_data_name:"Bacteria">, <proteins count : "1">	NA

We now show, with the aid of query QD1, how *DI* helps refine queries. For QD1, GKS returned a total of 30 XML nodes ($s=1$). The *DI* was <author: Marek Rusinkiewicz>. After analyzing the query response, QD1 is refined to ("Dimitrios Georgakopoulos", "Marek Rusinkiewicz"). Interestingly, for the refined query we found that there were 10 articles jointly written by these two authors as opposed to just 1 joint article by authors in original query. This is an example of how *GKS helps users refine their queries and guides them to navigate the data by recursive application of GKS.*

7.5 Crowd-Sourced Feedback: GKS & SLCA

We asked 40 users to compare the GKS response with SLCA response on a scale of 1-4; 1 being 'GKS Very Useful' and 4 being 'SLCA Very Useful'. Results are shown in the table below. For almost all the queries, *GKS* response is found to be either very useful (1) or better than SLCA (2). If we categorize the response as 'GKS-better' (rating 1 or 2) and 'SLCA-better' (rating 3 or 4), 430 out of 480 responses found the *GKS* response better (89.6%).

Query	1	2	3	4
QS1	24	16	0	0
QS2	17	22	1	0
QS3	17	14	5	4
QS4	12	22	3	4
QD1	24	15	1	0
QD2	18	17	3	2
QD3	20	18	1	1
QD4	24	13	3	0
QM1	16	20	3	1
QM2	15	18	5	2
QM3	14	18	5	3
QM4	16	21	3	0

7.6 GKS Performance for Hybrid Queries

We further studied how well GKS behaves in the presence of clearly separable keywords in the query, i.e., subsets of the keywords in a query indeed refer to different entity type nodes. We call such queries 'hybrid queries'. To study GKS performance for hybrid queries, we merged DBLP and Sigmod Record datasets into a single dataset (with a 'common root'). We also increased the depth of Sigmod Record elements by introducing two connecting nodes between the 'common root' and the root of Sigmod Record data. We ran the query "Jean-Marc Meynadier" "Patrick Behm" "Lawrence A. Rowe" "Michael Stonebraker", $s=2$. First two authors appeared together only in <inproceedings> entity node type in DBLP dataset and last two in <article> entity node type in Sigmod Record. Clearly, the keywords in the query target two different XML node types. GKS was able to return all 8 corresponding XML nodes present in our dataset, 3 <inproceedings> nodes in DBLP data by first 2 authors and 5 <article> nodes in Sigmod Record data by last 2 authors. Thus, *GKS returned correct response even when multiple XML node types were targeted by a single query.* Note, only these 8 nodes were returned by GKS.

Further, two <article> nodes, by last two authors, were ranked higher (as they were the only authors in all the three articles) despite higher relative depth w.r.t. root (articles by first 2 authors had multiple other authors). Hence, *the entity nodes are ranked based on only the number of query keywords present in their sub-tree and the distribution of these keywords*, and not according to their absolute depth in the XML tree, as analyzed in Section 5.

Summary: In summary, experiments show that GKS is scalable, imposes low overhead and retrieves the XML nodes efficiently. The experiments validate our node categorization model and show that XML nodes and *DI* discovered by GKS are highly relevant

8. CONCLUSION

We presented a novel system GKS that enables generic keyword search over XML data and yields highly meaningful response without imposing the AND-Semantics of LCA based techniques. We show that our system exposes deeper analytical insights (*DI*) in the data in the context of user queries. GKS exploits the XML schema, embedded in the XML data, in the context of the query to find the most relevant data keywords and schema elements with the aid of a novel node categorization model. In conjunction with a novel XML node ranking method, GKS is able to expose the *DI* elegantly. One of our future research direction is to extend GKS to enable analytics over raw XML data.

ABSTRACT

Keyword search over relational databases has gained popularity as it provides a user-friendly way to explore structured data. Current research in keyword search has largely ignored queries to retrieve statistical information from the database. The work in [13] extends keywords by supporting aggregate functions in their SQAK system. However, SQAK does not consider the semantics of objects and relationships in the database, and thus suffers from the problems of returning incorrect answers. In this work, we propose a semantic approach to answer keyword queries involving aggregates and GROUPBY. Our approach utilizes the ORM schema graph to capture the Object-Relationship-Attribute (ORA) semantics in the database, and determines the various interpretations of a query before generating the corresponding SQL statements. These semantics enable us to distinguish objects with the same attribute value and detect duplications of objects in relationships to compute the answers correctly. Our approach can also handle unnormlized relations in the database and GROUPBY in keyword queries which SQAK cannot. Experiments on the TPC-H and ACM Digital Library publication datasets demonstrate the advantages of the proposed semantic approach in retrieving correct statistical information for users.

1. INTRODUCTION

As databases increase in size and complexity, the ability for users to issue structured queries in SQLs has become a challenge. Keyword search over relational databases has gained traction as it enables users to query the database without knowing the database schema or having to write complicated SQL queries [7, 10, 8, 1, 2]. Research on relational keyword search has focused on the efficient computation of the minimal set of tuples that contain all the query keywords [9, 6, 5, 4], and strategies to retrieve relevant answers to the query [6, 10, 14, 3]. However, these works do not handle keyword queries involving aggregate functions and GROUPBY. We call these aggregate queries.

Aggregate queries is a powerful mechanism that provides users with a summary of the data. The work in [13] developed a prototype system called SQAK that allows aggregate queries to be expressed using simple keywords. An aggregate query in SQAK comprises of a set of terms and one of the terms is an aggregate function such as *COUNT*, *SUM*, *AVG*, *MIN*, or *MAX*. SQAK models the database schema as a schema graph where each node represents a relation and each edge represents a foreign key-key reference. Then SQAK identifies the matches of each term in a query. A relation is matched if a term matches its name, or the name of one of its attributes, or the value of some of its tuples. A set of minimal connected subgraphs of the schema graph that contain the matched relations are generated. These subgraphs are translated into SQL statements to retrieve answers from the database. Note that an aggregate function(s) is applied to the attribute that follows the aggregate term in the query.

Figure 1 shows a sample university database. Suppose we want to know the total credits obtained by the student Green. We can issue a keyword query $Q_1 = \{\text{Green SUM Credit}\}$, where the term SUM indicates the aggregate function *SUM* on the course credits, and SQAK will generate the following SQL statement for the query:

```
SELECT S.Sname, SUM(C.Credit)
FROM Student S, Enrol E, Course C
WHERE E.Sid=S.Sid AND E.Code=C.Code
AND S.Sname='Green' GROUP BY Sname
```

Student			Course			Enrol			Teach

Figure 1: Example university database

We observe that SQAK may compute incorrect answers when a query term matches multiple tuples. We see that the term *Green* in Q_1 matches the names of two students s_2 and s_3 in Figure 1. This naturally implies that we should find the sum of the credits obtained by each of these students,

i.e., the total credits for *s2* is 5 while the total credits for *s3* is 8. However, SQAK does not distinguish between these two “different” name matches, and outputs a total credits of 13 for students called **Green**, which is incorrect.

Similarly, SQAK may return incorrect answers when a query matches a relation that has more than 2 foreign keys. For instance, the *Teach* relation in Figure 1 contains 3 foreign keys that reference the relations *Course*, *Lecturer* and *Textbook* respectively, and depicts that a course can be taught by more than one lecturer using different textbooks. Suppose we have a query $Q_2 = \{\text{Java SUM Price}\}$, where the term **Java** matches a course title while the term **Price** matches an attribute of the *Textbook* relation. This implies that we should return the total price of the textbooks that are used in the **Java** course. Based on the *Teach* relation, there are 2 such textbooks *b1* and *b2* whose total price is 25. But SQAK will generate the following SQL statement:

```
SELECT C.Title, SUM(B.Price)
FROM Course C, Teach T, Textbook B
WHERE T.Bid=B.Bid AND T.Code=C.Code
AND C.Title='Java' GROUP BY C.Title
```

which returns 35 for total price because textbook *b1* appears 2 times for the **Java** course (i.e., *c1*) in the *Teach* relation. This answer is incorrect as a student does not need 2 copies of the same textbook for a course.

In addition, many applications often denormalize their databases to improve runtime performance. This denormalization leads to data duplication which affects the database schema graph. As SQAK does not consider unnormalized relations in the database, it will return incorrect answers for aggregate queries.

Figure 2 shows an unnormalized university database where the *Lecturer* relation now has a foreign key that references the *Faculty* relation. Consider the query $Q_3 = \{\text{Engineering COUNT Department}\}$, where the term **Engineering** matches a faculty name while the term **Department** matches the name of the *Department* relation. SQAK will find the number of departments in **Engineering** faculty by joining the relations *Department*, *Lecturer* and *Faculty*, and output an incorrect answer 2. This is because the values of attributes *Did* and *Fid* in the *Lecturer* relation are duplicated.

Lecturer				Department		Faculty	
Lid	Lname	Did	Fid	Did	Dname	Fid	Fname
l1	Steven	d1	f1				
l2	George	d1	f1	d1	CS	f1	Engineering

Figure 2: An unnormalized university database

We advocate that a relational database is essentially a repository of objects that interact with each other via relationships that are embedded in foreign key-key references. Since SQAK does not consider the semantics of objects and relationships in the database, it will not be able to distinguish objects with the same attribute value (as in Q_1), and it will fail to detect the duplications of objects in relationships (as in Q_2). This leads to the incorrect computations of aggregate queries. Further, if relations are unnormalized with duplicate information of objects and relationships, SQAK may compute the same information repeatedly and return incorrect answers to aggregate queries (as in Q_3).

In this paper, we propose a semantic approach to answer keyword queries involving aggregates and GROUPBY on re-

lational databases. Our approach utilizes the ORM schema graph introduced in [15] to capture the Object-Relationship-Attribute (ORA) semantics in the database. Given an aggregate query, we analyze the context of query keywords, interpret the various interpretations of the query and then apply aggregate functions and GROUPBY on the appropriate attributes of objects/relationships based on the ORM schema graph. Each query interpretation is denoted as a minimal connected graph called annotated query pattern. The top-k ranked annotated query patterns are translated into SQL statements to compute the answers to the aggregate query. By using the ORA semantics, we can distinguish the objects with the same attribute value as well as detect the duplications of objects in relationships in order to avoid incorrect computations of aggregate functions. Otherwise, it is impossible to answer aggregate queries correctly. We also develop a mechanism to detect duplicate information of objects/relationships arising from unnormalized relations so that the aggregate functions will not repeatedly compute statistics for the same information.

The contributions of our work are summarized as follows:

1. We examine how SQAK answers aggregate queries in relational keyword search, and identify its problems of returning incorrect answers due to its unawareness of the ORA semantics in the database.
2. We extend the keyword query language to incorporate aggregates and GROUPBY, and propose a semantic approach to process aggregate queries. We show that without the ORA semantics, it is impossible to process the aggregate functions correctly.
3. By using the ORA semantics, we detect the duplications of objects and relationships arising from unnormalized relations, and extend our approach to handle aggregate queries on unnormalized databases correctly.
4. We conduct extensive experiments to demonstrate the correctness of our approach in retrieving statistical information for users.

2. PRELIMINARIES

The work in [15] extends the keyword query language to include keywords that match meta-data, i.e., the names of relations and attributes. These keywords reduce query ambiguity by providing the context of subsequent keywords in the query.

Consider the query $\{\text{Lecturer George}\}$ on the database in Figure 1. The keyword **George** can refer to a student name or a lecturer name. However, since the keyword **Lecturer** matches the name of the relation *Lecturer* and provides the context of the keyword **George**, we deduce that the user is more likely to be interested in a lecturer named **George** rather than a student. Here, we further extend the query language to incorporate aggregates and GROUPBY.

DEFINITION 1. A keyword query Q is a sequence of terms $\{t_1 t_2 \dots t_n\}$ where each term t_i either matches a relation name, an attribute name, a tuple value, GROUPBY or an aggregate function MIN, MAX, AVG, SUM or COUNT.

In order to properly interpret a keyword query involving aggregate functions and GROUPBY, we impose the following constraints on the terms in the query:

1. The last term t_n cannot match an aggregate function or GROUPBY.
2. For each term t_i , $i < n$ that matches the aggregate function MIN , MAX , AVG or SUM , the next term t_{i+1} should match an attribute name.
3. For each term t_i , $i < n$ that matches $COUNT$ or GROUPBY, the next term t_{i+1} should match either a relation name or an attribute name.

A query that satisfies the last constraint is {COUNT Student GROUPBY Course}. An SQL statement to find the number of students in each course is generated as follows:

```
SELECT C.Code, COUNT(S.Sid) As numSid
FROM Student S, Enrol E, Course C
WHERE E.Sid=S.Sid AND E.Code=C.Code
GROUPBY C.Code
```

Note that the terms Student and Course match the names of the *Student* and *Course* relations, and are mapped to *Sid* and *Code* respectively.

2.1 Query Patterns

The work in [16] classifies the relations in a database into object relations, relationship relations, mixed relations and component relations. An object (relationship resp.) relation captures the information of objects (relationships resp.), i.e., the single-valued attributes of an object class (relationship type). Multivalued attributes of an object class (relationship type) are captured in object/relationship component relations. A mixed relation contains information of both objects and relationships, which occurs when we have a many-to-one relationship. We call these semantics the Object-Relationship-Attribute (ORA) semantics.

A keyword query is inherently ambiguous as each keyword can have multiple matches. [15] introduces the notion of query patterns to depict the interpretations of a keyword query. These query patterns are generated from the Object-Relationship-Mixed (ORM) schema graph of the database. The ORM schema graph is an undirected graph that captures the ORA semantics in the database. Each node in the ORM schema graph comprises of an object/relationship/mixed relation and its component relations, and is associated with a type (object, relationship and mixed). Two nodes are connected if there exists a foreign key - key reference between the relations in these two nodes.

In Figure 1, the relations *Student*, *Course*, *Faculty* and *Textbook* are object relations while *Enrol* and *Teach* are relationship relations. Relations *Lecturer* and *Department* are mixed relations because of the many-to-one relationships between lecturers and departments, and the many-to-one relationships between departments and faculties respectively. Figure 3 shows the ORM schema graph of the database.

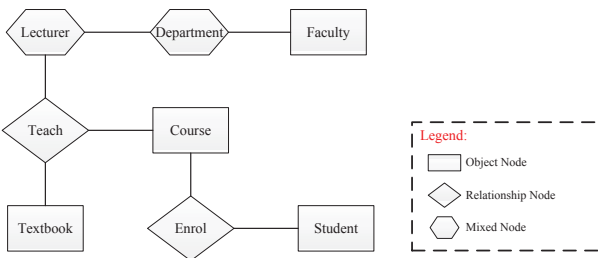

Figure 3: ORM schema graph of Figure 1

A query pattern for the keyword query {Green George Code} is shown in Figure 4. This pattern depicts the query interpretation to find the common courses taken by students Green and George. We generate this pattern by first identifying the matches of each term in the query. The term Code matches the name of an attribute in the *Course* relation, while both terms Green and George match some tuple value in the *Student* relation, specifically, the value of *Sname* attribute. Based on these matches, we know that Green and George refer to two student objects and Code refers to a course object. Thus, we create 2 Student nodes and 1 Course node to represent these objects. From the ORM schema graph in Figure 3, we know that the Student node and the Course node are connected via an Enrol node. Hence, we create 2 Enrol nodes and obtain the query pattern in Figure 4.

Figure 4: Query pattern of {Green George Code}

Note that the term George can refer to a lecturer object since it also matches some tuple value in the *Lecturer* relation. Hence, this keyword query has more than one query pattern. We rank these query patterns and translate the top-k ranked patterns into SQL statements.

In this work, we want to utilize these query patterns to capture the interpretations of an aggregate query. However, since we extend the keyword query to include GROUPBY and aggregate functions, we need to annotate the nodes that the GROUPBY and aggregate functions are applicable to. Annotating the appropriate nodes is important as it will facilitate the translation of the query pattern into SQL statements to retrieve the correct answers for the aggregate query. We will discuss how we achieve this in the next section.

3. AGGREGATE QUERIES ON NORMALIZED DATABASE

3.1 Simple Aggregate Queries

Given a keyword query $Q = \{t_1 t_2 \dots t_n\}$, we first classify the terms t_i into *basic terms* and *operators*. A basic term matches a relation name, or an attribute name, or a tuple value, while an operator matches GROUPBY or an aggregate function. Then we process Q as follows:

1. **Pattern generation and annotation.** We utilize the ORM schema graph of the database and the basic terms in the query to generate a set of query patterns, and annotate these patterns with the operators.
2. **Pattern disambiguation.** We disambiguate the query patterns by annotating the object/mixed nodes with GROUPBY. This is to distinguish objects with the same attribute value in the database.
3. **Pattern translation.** We translate the top-k ranked query patterns into SQL statements to compute the aggregate functions in the query.

We explain the details of these steps next.

3.1.1 Pattern Generation and Annotation

We use the basic terms in a query to generate a set of initial query patterns. Each pattern P contains a set of

nodes that represent the objects or relationships referred to by the basic terms. The nodes are connected based on the ORM schema graph as described in [15]. A node is annotated with the condition $a = t$ if the basic term t refers to the value of the attribute a of the object/relationship.

For each operator $t_i \in Q$, we examine the matches of its subsequent term t_{i+1} in Q to annotate query pattern P . We have two cases:

- t_{i+1} matches the name of some object/ mixed/ relationship relation.

This indicates that t_{i+1} refers to some object or relationship, and the operator t_i is applied on the identifier id of this object/relationship. We annotate the node that represents this object/relationship in P with $t_i(id)$, id is given by the primary key of the relation.

- t_{i+1} matches the name of a component relation or an attribute name.

This indicates that t_{i+1} refers to some attribute a of an object or relationship, and t_i is applied on this object/relationship attribute. We annotate the node that represents this object/relationship in P with $t_i(a)$.

EXAMPLE 1. Consider query $Q_4 = \{\text{Green George COUNT Code}\}$. Figure 4 shows a query pattern obtained using the basic terms *Green*, *George* and *Code*. For the operator *COUNT*, its subsequent term *Code* matches an attribute name in the *Course* relation. Hence, we annotate the *Course* node with *COUNT(Code)*. Figure 5(a) shows the annotated query pattern P_1 that depicts the query interpretation to find the total number of courses taken by students *Green* and *George*. \square

EXAMPLE 2. Query $Q_5 = \{\text{COUNT Lecturer GROUPBY Course}\}$ has two basic terms *Lecturer* and *Course*. We generate a query pattern that contains a *Teach* relationship node between the objects *Lecturer* and *Course*. For the operator *GROUPBY*, since its subsequent term *Course* matches the name of the *Course* relation, and refers to a course object, we obtain the identifier of the course object and annotate the corresponding *Course* node in the query pattern with *GROUPBY(Code)*. Similarly, operator *COUNT* has a subsequent term *Lecturer* that matches the name of the *Lecturer* relation. We annotate the *Lecturer* node with *COUNT(Lid)* and obtain the annotated query pattern P_2 in Figure 5(b). This query pattern indicates that the user is interested in the number of lecturers for each course. \square

Figure 5: Annotated query patterns of Q_4 and Q_5

3.1.2 Pattern Disambiguation

After annotating the query pattern with operators, we examine the object and mixed nodes in the pattern. An object/mixed node with the condition $a = t$ refers to an

object such that its value of attribute a matches the basic term t . However, since this condition could be satisfied by more than one object in the database, there are two different interpretations of t in the context of the aggregate query:

1. Apply the aggregate function(s) for every *distinct* object satisfying the condition $a = t$.
2. Apply the aggregate function(s) for *all* the objects satisfying the condition $a = t$.

These two interpretations will lead to different results of the aggregate function(s) and we need to distinguish them in the annotated query pattern. Note that SQAK does not distinguish objects satisfying the same condition, and thus returns incorrect answers to the query.

Let P be an annotated query pattern for aggregate query Q and U be a set of object/mixed nodes in P . We generate a set of patterns S to indicate if objects with the same value will be distinguished for aggregates. Initially, S only contains the pattern P . For each node $u \in U$ that is annotated with the condition $a = t$, we check if more than one object satisfies this condition in the database. If so, we create a copy of each pattern in S to indicate if objects that satisfy the condition $a = t$ will be distinguished in these patterns. Let P_1 be a pattern in S and P_2 be a copy of P_1 . We annotate u in P_2 with *GROUPBY(id)*, where id is the identifier of the object referred to by u . In particular, P_1 indicates that aggregate function(s) is applied for all the objects that satisfy $a = t$, while P_2 indicates that aggregate function(s) is applied for every distinct object with $a = t$.

EXAMPLE 3. Consider the query pattern P_1 for the query $Q_4 = \{\text{Green George COUNT Code}\}$ in Figure 5(a). This pattern contains three object/mixed nodes: one *Course* node and two *Student* nodes that are annotated with the conditions *Sname = Green* and *Sname = George* respectively. For the *Student* node imposed by the condition *Sname = George*, we do not need to create new copies of query patterns as there is only one student called *George* in Figure 1. However, for the *Student* node imposed by the condition *Sname = Green*, we know that there are two students called *Green* in Figure 1. Hence, we create a copy P_3 of the pattern P_1 and annotate this node with *GROUPBY(Sid)* in P_3 . Figure 6 shows the query pattern P_3 . It indicates that the aggregate function counts the number of courses enrolled by each student called *Green*. In contrast, pattern P_1 indicates that the count aggregate is applied for both these two students. \square

Figure 6: A query pattern for Q_4

Next, we rank the query patterns. [15] classifies nodes in a query pattern into target nodes and condition nodes. A target node specifies the search target of the query, and a condition node indicates the search conditions of the query. A query pattern is ranked based on its number of object/mixed

nodes and the average distance between the target and condition nodes. Patterns with fewer object/mixed nodes, and a shorter average distance are ranked higher.

Here, we extend the definitions of target nodes and condition nodes to rank the query patterns of an aggregate query. Let P be an annotated query pattern and u be a node in P . We say u is a target node if u is annotated with an aggregate function. Otherwise, u is a condition node if u is annotated with a condition or GROUPBY. We can now use the same method as [15] to rank the annotated query patterns.

3.1.3 Pattern Translation

Finally, we translate the top-k ranked query patterns into SQL statements. A straightforward way to translate an annotated query pattern is to join the relations of all the nodes in the pattern, select the tuples that satisfy the conditions imposed by basic terms from the join result, and then apply GROUPBY and aggregate function(s) on the selected tuples. However, this may generate an SQL statement that gives an incorrect answer to the query.

EXAMPLE 4. Consider the query pattern P_2 for the query $Q_5 = \{\text{COUNT Lecturer GROUPBY Course}\}$ in Figure 5(b). If we simply translate P_2 into an SQL statement that joins the relations *Teach*, *Lecturer* and *Course*, and applies the count aggregate on the lecturer id *Lid* after grouping the tuples by the course code, we may obtain wrong answers as the same lecturer may be counted multiple times. This is because the *Teach* node in P_2 is in fact a ternary relationship involving the objects *course*, *lecturer* and *textbook* (see the ORM schema graph in Figure 3). Since different *Bid* may have the same *Lid* and *Code*, we should project the *Teach* relation on the foreign keys $\langle \text{Lid}, \text{Code} \rangle$ to remove duplicates before joining with the relations *Lecturer* and *Course*. \square

The above example demonstrates the need to examine the type of nodes in a query pattern if we want to generate the SQL statement correctly. In particular, if the query pattern contains a relationship node u , we should look at its corresponding node v in the ORM schema graph to determine if a projection is needed to remove duplicates. Note that SQAk does not detect the duplications of objects in relationships, and suffers from the problem of returning incorrect answers.

Given a query pattern P , we generate the clauses in an SQL statement as follows:

SELECT clause. If a node $u \in P$ is annotated with $t(a)$ and t matches an aggregate function, we include t in the SELECT clause. t is applied on attribute a . If u is annotated with $\text{GROUPBY}(a)$, we include a in the SELECT clause to facilitate user understanding of the aggregate function(s).

FROM clause. This clause includes the relations of all the nodes in P . For each relationship node $u \in P$, we check its corresponding node v in the ORM schema graph. Let $N_u = \{u_1, u_2, \dots, u_x\}$ be a set of object/mixed nodes that are directly connected to u in P , and $N_v = \{v_1, v_2, \dots, v_y\}$ be the set of object/mixed nodes that are directly connected to v in the ORM schema graph. If $x < y$, then this indicates that P contains a subset of the participating objects of the relationship v , and we project the foreign keys k_1, k_2, \dots, k_x in the relation of u such that k_i references the relation of u_i in N_u , $i \in [1, x]$. This projection eliminates duplicates and we replace the relation of u in the FROM clause with the relation obtained by this projection.

WHERE clause. The WHERE clause joins all the relations in the FROM clause based on foreign key - key references. For each node $u \in P$ that is annotated with a condition $a = t$, we include the condition “ $R_u.a$ contains t ” where R_u is the relation corresponding to u .

GROUPBY clause. If a node u is annotated with $t(a)$ and t matches GROUPBY, then we include the attribute a in the GROUPBY clause.

EXAMPLE 5. The query pattern P_3 in Figure 6 for query $Q_4 = \{\text{Green George COUNT Code}\}$ depicts the total number of courses enrolled by the student *George* and each of the students called *Green*. The *Course* node is annotated with $\text{COUNT}(\text{Code})$, thus we include $\text{COUNT}(\text{Code})$ in the SELECT clause. The FROM clause contains the relations corresponding to each of the nodes in P_3 . Next, we add the conditions to join these relations in the WHERE clause, as well as the conditions in the two annotated *Student* object nodes. Since the *Student* node imposed by the condition $\text{Sname} = \text{Green}$ is also annotated with GROUPBY to distinguish different students called *Green*, we include the id of its relation in the GROUPBY clause, and obtain the SQL statement:

```
SELECT S1.Sid, COUNT(C.Code) AS numCode
FROM Course C, Enrol E1, Student S1, Enrol E2, Student S2
WHERE C.Code=E1.Code AND C.Code=E2.Code
      AND S1.Sid=E1.Sid AND S1.Sname contains 'Green'
      AND S2.Sid=E2.Sid AND S2.Sname contains 'George'
GROUP BY S1.Sid
```

By applying GROUPBY on student ids, we distinguish students s_2 and s_3 who have the same name *Green*, and the aggregate function COUNT is computed for the courses of each student. \square

EXAMPLE 6. The query pattern P_2 in Figure 5(b) for query $Q_5 = \{\text{COUNT Lecturer GROUPBY Course}\}$ depicts the number of lecturers for each course. The *Lecturer* node is annotated with $\text{COUNT}(\text{Lid})$ while the *Course* node is annotated with $\text{GROUPBY}(\text{Code})$. Hence, we include the aggregate function $\text{COUNT}(\text{Lid})$ in the SELECT clause, and the attribute *Code* in the GROUPBY clause. The *Teach* node in P_2 is connected to two object/mixed nodes, while the corresponding *Teach* node in the ORM schema graph in Figure 3 is connected to three object/mixed nodes. We generate a subquery “SELECT DISTINCT *Lid*, *Code* FROM *Teach*” to project the attributes *Lid* and *Code* in the *Teach* relation. The subquery has a DISTINCT keyword and thus eliminates any duplicates of $\langle \text{Lid}, \text{Code} \rangle$ for different *Bid*. We use the result of this subquery to join the other relations in the FROM clause. The SQL statement generated is:

```
SELECT C.Code, COUNT(L.Lid) AS numLid
FROM Lecturer L, Course C,
      (SELECT DISTINCT Lid, Code FROM Teach) T
WHERE T.Lid=L.Lid AND T.Code=C.Code
GROUP BY C.Code
```

\square

3.2 Nested Aggregate Queries

So far, we have described how to handle keyword queries involving simple aggregate functions and GROUPBY. In order to maximize the power of aggregate queries, we also want to support queries with nested aggregate functions.

Given a keyword query $Q = \{t_1 t_2 \dots t_n\}$, we relax the constraints on the terms so that if the term t_i , $i < n$ matches

an aggregate function, the next term t_{i+1} can also match an aggregate function. In this case, the aggregate function t_i is applied on the result of the aggregate function t_{i+1} .

Let P be a query pattern obtained from basic terms in the query. We annotate P with $t_i(f)$, where f is the attribute name assigned to the result of aggregate function t_{i+1} . Then we generate a nested SQL statement for P . The inner query computes the aggregate function t_{i+1} , while the outer query includes the inner query in the FROM clause and computes the aggregate function t_i .

EXAMPLE 7. Suppose the user issues a query $\{AVG\ COUNT\ Lecturer\ GROUPBY\ Course\}$ to find the average number of lecturers that teach a course. Both the terms AVG and $COUNT$ match some aggregate function. We obtain the query pattern and annotate the operators $COUNT$ and $GROUPBY$. For the AVG operator, we annotate the pattern with $AVG(numLid)$, where $numLid$ is the attribute name given to the result of the aggregate function $COUNT$. Figure 7 shows the annotated query pattern. We translate the query pattern by first generating an inner SQL query similar to that in Example 6. Then we put it in the FROM clause of the outer SQL query to compute the aggregate function AVG as follows:

```
SELECT AVG(R.numLid) AS avgnumLid
FROM ( SELECT C.Code, COUNT(L.Lid) AS numLid
      FROM Lecturer L, Course C,
           (SELECT DISTINCT Lid, Code FROM Teach) T
      WHERE T.Lid=L.Lid AND T.Code=C.Code
      GROUP BY C.Code) R
```

□

Figure 7: Query pattern in Example 7

4. AGGREGATE QUERIES ON UNNORMALIZED DATABASE

Relations in a relational database are often unnormalized to reduce the number of joins and improve query processing performance. A relational database that contains unnormalized relations is called an unnormalized database. The denormalization process will duplicate information in the database and SQAk may obtain incorrect results for keyword queries involving aggregates.

Recall that in Figure 2, the *Lecturer* relation is denormalized by adding a foreign key *Fid* that references the *Faculty* relation. This allows queries that are frequently issued on lecturers and their faculties to be answered quickly without the need to join the *Department* relation. Given a query $Q_3 = \{\text{Engineering COUNT Department}\}$, SQAk will join the relations *Lecturer*, *Department* and *Faculty* and return incorrect number of departments in the *Engineering* faculty as it does not handle unnormalized relations.

In order to generate SQL statements correctly for keyword queries involving aggregates, we need to determine if relations are unnormalized. This can be done by examining the functional dependencies that hold on the relations.

Consider the unnormalized relation *Enrolment* in Figure 8 that is obtained by joining the *Student*, *Enrol* and *Course* relations in Figure 1. The following functional dependencies hold on the *Enrolment* relation:

- $Sid \rightarrow Sname, Age$
- $Code \rightarrow Title, Credit$
- $Sid, Code \rightarrow Grade$

We deduce that $\{Sid, Code\}$ is the key of the *Enrolment* relation, and it violates the second normal form (2NF) definition as *Sname* and *Age* only depend on *Sid*.

Sid	Sname	Age	Code	Title	Credit	Grade
s1	George	22	c1	Java	5.0	A
s1	George	22	c2	Database	4.0	B
s1	George	22	c3	Multimedia	3.0	B
s2	Green	24	c1	Java	5.0	A
s3	Green	21	c1	Java	5.0	A
s3	Green	21	c3	Multimedia	3.0	B

Figure 8: An unnormalized relation

A naive approach to handle a keyword query involving aggregate functions on the unnormalized database is to generate a copy of the database where every relation is normalized and then process the query as described in Section 3. However, this approach is expensive and not feasible in practice.

We observe that although the relations are unnormalized, the information of objects and relationships in the database remain the same. Hence, if we can keep track of the objects and relationships information in an unnormalized database, then we can continue to process keyword queries involving aggregates and $GROUPBY$ correctly.

Recall that the ORM schema graph captures the information of objects and relationships in the database by classifying the relations into different types. These relations are assumed to be in 3NF. Thus, we generate a *normalized view* of the unnormalized database comprising of a minimal set of relations in 3NF. Then we classify the relations in this normalized view and construct the ORM schema graph to represent the ORA semantics in the unnormalized database.

Let $D = \{R_1, R_2, \dots, R_j\}$ be the set of relations in the original unnormalized database schema, and D' be the set of relations in the normalized view. For each $R_i \in D$, $1 \leq i \leq j$, if R_i is in 3NF, then we add it to D' . Otherwise, we normalize R_i into a set of relations in 3NF and add them to D' . Finally, relations in D' with the same key are merged. We use relational algebra operators to express the mappings of the relations from D to D' , and vice versa.

EXAMPLE 8. Let us generate the normalized view of the unnormalized database in Figure 8. The database consists of a single relation *Enrolment* and has the schema D below:

Enrolment(*Sid*, *Code*, *Sname*, *Age*, *Title*, *Credit*, *Grade*)

Since the *Enrolment* relation is not in 3NF, we decompose it into 3NF relations *Student'*, *Enrol'* and *Course'*. Thus, the normalized view D' will have the relations:

Student'(*Sid*, *Sname*, *Age*)

Enrol'(*Sid*, *Code*, *Grade*)

Course'(*Code*, *Title*, *Credit*)

Based on D' , we construct the ORM schema graph of the unnormalized database as shown in Figure 9. Table 1 shows the mappings of the relations in D and D' . □

Figure 9: ORM schema graph of Figure 8

Table 1: Mappings of relations in Example 8

$Student' = \Pi_{Sid, Sname, Age}(Enrolment)$
$Enrol' = \Pi_{Sid, Code, Grade}(Enrolment)$
$Course' = \Pi_{Code, Title, Credit}(Enrolment)$

(a) From original schema D to normalized view D'

$Enrolment = Student' \bowtie Enrol' \bowtie Course'$

(b) From normalized view D' to original schema D

After obtaining the normalized view D' and the ORM schema graph G of the unnormalized database with schema D , we can proceed to evaluate an aggregate query Q on D correctly as follows:

First, we identify the matches of each basic term in the unnormalized database. Let R be the relation in D such that a basic term t matches the relation name of R , or the name of an attribute in R , or the value of some tuples in R . We obtain the corresponding relations of R in D' based on the mappings from D to D' .

Next, we utilize the relations in D' to generate the query patterns based on G , and annotate these patterns with the operators in the query as described in Section 3. Note that the generated query patterns are based on the normalized view D' , since G is constructed from D' .

Finally, we translate the annotated query patterns into SQL statements to be executed over the original unnormalized database. This requires us to map the relations in D' back to their corresponding relations in D . Depending on the mappings, a relation R' that corresponds to a node in the query pattern may become a subquery in SQL.

EXAMPLE 9. Consider query $Q_4 = \{Green\ George\ COUNT\ Code\}$ on the unnormalized database in Figure 8. The terms *Green* and *George* match the *Sname* attribute values of some tuples in the *Enrolment* relation, while the term *Code* matches the name of an attribute in *Enrolment*.

Based on Table 1(a), these matches correspond to 2 *Student'* relations and 1 *Course'* relation in the normalized view of the database respectively, indicating that *Green* and *George* refer to two student objects, while *Code* refers to a course object. Based on the ORM schema graph in Figure 9, we generate a query pattern that connects 2 *Student'* nodes and 1 *Course'* node via 2 *Enrol'* nodes, and annotate it with operators *COUNT* and *GROUPBY*.

Figure 10 shows the query pattern obtained. It depicts the query interpretation to find the total number of courses taken by the student *George* and each student called *Green*. We use the mappings in Table 1(b) to translate the query pattern and obtain an SQL statement with 5 subqueries, namely, 2 subqueries for *Student'* relation, 2 subqueries for *Enrol'* relation, and 1 subquery for *Course'* relation in the normalized view of the database.

Figure 10: Query pattern in Example 9

```
SELECT S1'.Sid, COUNT(C'.Code) AS numCode FROM
  (SELECT DISTINCT Code, Title, Credit FROM Enrolment) C',
  (SELECT Sid, Code, Grade FROM Enrolment) E1',
  (SELECT DISTINCT Sid, Sname, Age FROM Enrolment) S1',
  (SELECT Sid, Code, Grade FROM Enrolment) E2',
  (SELECT DISTINCT Sid, Sname, Age FROM Enrolment) S2'
WHERE C'.Code=E1'.Code AND C'.Code=E2'.Code
  AND S1'.Sid=E1'.Sid AND S1'.Sname contains 'Green'
  AND S2'.Sid=E2'.Sid AND S2'.Sname contains 'George'
GROUP BY S1'.Sid
```

□

4.1 Query Rewriting

The generated SQL statement may contain a lot of subqueries since the mapping from a relation $R' \in D'$ to a relation $R \in D$ for a node in P often involves a subset of the attributes of R . Joining relations obtained from subqueries is time consuming due to the lack of indexes. Hence, it is crucial to rewrite the SQL to improve query performance.

We observe that some attributes in the SELECT clause of subqueries are never used, and can be removed. In Example 9, we can rewrite the subquery “SELECT DISTINCT Code, Title, Credit FROM Enrolment” to “SELECT DISTINCT Code FROM Enrolment”, since Title and Credit are not used.

Further, some select conditions in the SQL statement can be moved to the WHERE clause of subqueries so that tuples can be filtered out before the join, e.g., we can rewrite the subquery “SELECT DISTINCT Sid, Sname, Age FROM Enrolment” to “SELECT DISTINCT Sid, Sname, Age FROM Enrolment WHERE Sname contains 'Green'” to filter out the students whose names are not Green.

Finally, relations are unnormalized to reduce the number of joins. We can try to use the unnormalized relation to replace the joining of relations obtained from subqueries. For example, the *Enrolment* relation is equivalent to the joins of relations obtained from the subqueries “SELECT DISTINCT Code, Title, Credit FROM Enrolment”, “SELECT Sid, Code, Grade FROM Enrolment”, and “SELECT DISTINCT Sid, Sname, Age FROM Enrolment”. Hence, we can use the *Enrolment* relation to replace these subqueries.

Based on the above observations, We derive the following heuristics to rewrite an SQL statement *sql* for the unnormalized database:

Rule 1: If a subquery projects an attribute that does not appear in the SELECT and WHERE clause of *sql*, then remove this attribute.

Rule 2: If a subquery projects an attribute a that appears in the condition “ a contains t ” of *sql*, then put this condition in the WHERE clause of the subquery.

Rule 3: Let s_1, s_2, \dots, s_m be a set of subqueries in *sql*. If there exists a relation R such that $s_1 \bowtie s_2 \bowtie \dots \bowtie s_m = \Pi_L(R)$, where L is a superkey of R , then replace $s_1 \bowtie s_2 \bowtie \dots \bowtie s_m$ with R .

EXAMPLE 10. Consider the SQL statement in Example 9. Since the joins of the subqueries “SELECT DISTINCT Code, Title, Credit FROM Enrolment”, “SELECT Sid, Code, Grade FROM Enrolment”, and “SELECT DISTINCT Sid, Sname, Age FROM Enrolment” is equivalent to the Enrolment relation, we replace $C' \bowtie E1' \bowtie S1'$ by the Enrolment relation. Further, we see that the joins of the subqueries “SELECT Sid, Code, Grade FROM Enrolment” and “SELECT DISTINCT Sid, Sname, Age FROM Enrolment” is equivalent to a relation obtained by projecting a super key (Sid, Code, Title, Credit, and Grade) of the Enrolment relation. Hence, we can also replace $E2' \bowtie S2'$ by the Enrolment relation, and obtain:

```
SELECT R1.Sid, COUNT(R1.Code) AS numCode
FROM Enrolment R1, Enrolment R2
WHERE R1.Code=R2.Code AND R1.Sname contains 'Green'
AND R2.Sname contains 'George'
GROUP BY R1.Sid
```

5. ALGORITHMS

Algorithm 1 generates a normalized view D' of the database schema D , if D is not normalized. For each relation R in D , if R is in 3NF, we add it into D' directly, otherwise we normalize R into a set of 3NF relations and add them into D' . After checking the relations in D , we enumerate each pair of relations R'_1 and R'_2 in D' . If R'_1 and R'_2 have the same key, then we merge them into a single relation R' .

After generating the database schema D and the normalized view D' , we obtain the mappings between D and D' . We call Algorithm 2 to process a keyword query Q and generate SQL statements. If the schema D is normalized, we construct the ORM schema graph G based on D . For each basic term t in Q , we find its matches in the database and create a tag for each of the matches to capture the interpretation of t . We insert these tags into a tag set $taglist$ (Lines 4-7). Based on $taglist$ and G , we generate a list of query patterns $ptnlist$ as described in [15], and annotate these patterns with the operators in Q (Lines 8-9). Then we translate each pattern P in $ptnlist$ into an SQL statement sql according to D , and insert it into $sqllist$ (Lines 10-12).

If the schema D is unnormalized, we construct the ORM schema graph G based on D' . For each basic term t , we create tags for t based on the matches in D and the mappings in D' . We generate a list of query patterns $ptnlist$ based on the tags and the ORM schema graph, and annotate each pattern P in $ptnlist$ with the operators. Then we translate each pattern P into an SQL statement sql based on D' , and map the relations of D' back to the relations of D in sql . Finally, we rewrite sql to sql' to reduce the number of subqueries and insert sql' into $sqllist$ (Lines 14-26).

Algorithm 3 annotates the query patterns. For each pattern P in $ptnlist$, we annotate P with operators. For each operator t in Q , let t' be the next term of t in Q . If t' is a basic term, we check its matches in D . Let u be a node in P and R be the relation of u . If t' matches the name of R , then we annotate u with $t(R.key)$; otherwise if t' matches an attribute a of R , we annotate u with $t(R.a)$. If t' is also an operator, then we annotate pattern P with $t(t')$ to indicate that t is a nested aggregate function (Lines 3-12). Next, we check the annotated nodes in the patterns. For each pattern P in $ptnlist$, we create a set S and add P into S . For each object/mixed node u in P , if u is annotated with the condition $a = t$, we find a set of tuples T that satisfy this

Algorithm 1: NormalizeDB

```
Input: database schema  $D$ 
Output: normalized view  $D'$ 
1  $D' \leftarrow \emptyset$ ;
2 foreach relation  $R$  in  $D$  do
3   if  $R$  is in 3NF then
4     Add  $R$  into  $D'$ ;
5   else
6     Normalize  $R$  into a set of 3NF relations  $F$ ;
7     foreach relation  $R'$  in  $F$  do
8       Add  $R'$  into  $D'$ ;
9 foreach pair of relations  $R'_1$  and  $R'_2$  in  $D'$  do
10  if  $R'_1.key = R'_2.key$  then
11    Merge  $R'_1$  and  $R'_2$  into  $R'$ ;
12 return  $D'$ ;
```

Algorithm 2: Keyword Search

```
Input: Query  $Q$ , database schema  $D$ , normalized view  $D'$ 
Output: a list of SQL statements  $sqllist$ 
1  $sqllist \leftarrow \emptyset$ ;  $ptnlist \leftarrow \emptyset$ ;  $taglist \leftarrow \emptyset$ ;
2 if  $D$  is normalized then
3    $G = \text{createORMGraph}(D)$ ;
4   foreach basic term  $t$  in  $Q$  do
5      $matches = \text{findMatch}(t, D)$ ;
6      $tagset = \text{createTag}(matches, G)$ ;
7     Insert  $tagset$  into  $taglist$ ;
8    $ptnlist = \text{createPattern}(taglist, G)$ ;
9    $ptnlist = \text{annotatePattern}(Q, ptnlist)$ ;
10  foreach Pattern  $P$  in  $ptnlist$  do
11     $sql = \text{translate}(P, D)$ ;
12    Insert  $sql$  into  $sqllist$ ;
13 else
14    $G = \text{createORMGraph}(D')$ ;
15   foreach basic term  $t$  in  $Q$  do
16      $matches = \text{findMatch}(t, D)$ ;
17     Map  $matches$  of  $D$  into  $matches'$  of  $D'$ ;
18      $tagset = \text{createTag}(matches', G)$ ;
19     Insert  $tagset$  into  $taglist$ ;
20    $ptnlist = \text{createPattern}(taglist, G)$ ;
21    $ptnlist = \text{annotatePattern}(Q, ptnlist)$ ;
22   foreach Pattern  $P$  in  $ptnlist$  do
23      $sql = \text{translate}(P, D')$ ;
24     Map the relations of  $D'$  to the relations of  $D$  in  $sql$ ;
25      $sql' = \text{rewrite}(sql)$ ;
26     Insert  $sql'$  into  $sqllist$ ;
27 return  $sqllist$ ;
```

condition in the relation of u . If T contains more than one tuple, we generate new copies of patterns in S to distinguish the objects that satisfy the same condition. For each pattern P in S , we create a copy P' of P , annotate node u in P' with $\text{GROUPBY}(R.key)$, and add P' into S . Finally, we add the patterns in S into the list $aptnlist$ (Lines 13-24).

6. PERFORMANCE STUDY

In this section, we evaluate the performance of our approach to process keyword queries involving aggregates and GROUPBY. We implement the algorithms in Java and carry out experiments on a 3.40 GHz CPU with 8 GB RAM. We use the relational databases TPC-H (TPCH) and ACM Digital Library publication (ACMDL). Table 2 shows the schemas of these databases. Tables 3 and 4 show the queries we constructed for each database and the corresponding descriptions (or search intentions).

Algorithm 3: Annotate Pattern

Input: query Q and a list of patterns $ptnlist$
Output: a list of annotated patterns $aptnlist$

```
1  $aptnlist \leftarrow \emptyset$ ;  
2 foreach Pattern  $P$  in  $ptnlist$  do  
3   foreach operator  $t$  in  $Q$  do  
4     Let  $t'$  be the next term of  $t$  in  $Q$ ;  
5     if  $t'$  is a basic term then  
6       Let  $u$  be a node in  $P$  and  $R$  be the relation of  $u$ ;  
7       if  $t'$  matches the name of  $R$  then  
8         Annotate  $u$  with  $t(R.key)$ ;  
9       else if  $t'$  matches an attribute  $a$  in  $R$  then  
10        Annotate  $u$  with  $t(R.a)$ ;  
11     else if  $t'$  is an operator then  
12       Annotate  $P$  with  $t(t')$ ;  
13 foreach Pattern  $P$  in  $ptnlist$  do  
14    $S = \{P\}$ ;  
15   foreach Object/Mixed node  $u$  in  $P$  do  
16     if  $u$  is annotated with condition  $a = t$  then  
17       Let  $R$  be the relation of  $u$  and  $T$  be the tuples  
18       satisfying  $a = t$  in  $R$ ;  
19       if  $|T| > 1$  then  
20         foreach Pattern  $P$  in  $S$  do  
21           Create a copy  $P'$  of  $P$ ;  
22           Annotate  $u$  in  $P'$  with  
23           GROUPBY( $R.key$ );  
24           Add  $P'$  into  $S$ ;  
25   Add the patterns in  $S$  into  $aptnlist$ ;  
26 return  $aptnlist$ ;
```

6.1 Effectiveness Experiments

Our approach utilizes the ORM schema graph to capture the ORA semantics in the database, and generates a list of annotated query patterns from the ORM schema graph to represent the various interpretations of a keyword query. Based on these patterns, we distinguish the objects with the same value and detect duplicate objects in relationships in order to compute the answers correctly.

We compare our approach with SQAK [13], the state-of-the-art relational keyword search engine that processes aggregate queries without considering the ORA semantics.

SQAK takes an aggregate query and finds a set of relations that are matched by query terms. A relation is matched if a term matches the name of the relation, or the name of one of its attributes, or the relation tuples. Based on these relations, it generates a set of minimal connected graphs called simple query networks (SQN). The SQNs are used to generate the SQL statements to return the answers.

6.1.1 Results for TPCB Database

We use the generated SQL statements that best match the query descriptions in Table 3 to compute the query answers. Table 5 shows the results returned by SQAK and our approach, as well as explanations for these answers. Although both SQAK and our approach give the same answer for queries $T1$ and $T2$, they differ greatly for the rest.

Queries $T3$ and $T4$ show that our approach is able to distinguish the various interpretations of query terms that match objects with the same value. For query $T3$, our approach returns the number of orders for each “royal olive” part, while SQAK returns the number of orders for all the “royal olive” parts. This is because we differentiate parts with the same name by their object identifiers `partkey`. Similarly, for $T4$, our approach returns the maximum account

Table 2: Database schemas

TPCH
Part(partkey, pname, type, size, retailprice)
Supplier(suppkey, sname, nationkey, acctbal)
Lineitem(partkey, suppkey, orderkey, quantity)
Order(orderkey, custkey, amount, date, priority)
Customer(custkey, cname, nationkey, mktsegment)
Nation(nationkey, nname, regionkey)
Region(regionkey, rname)

ACMDL
Paper(paperid, procid, date, ptitle)
Author(authorid, fname, lname)
Editor(editorid, fname, lname)
Proceeding(procid, acronym, title, date, pages, publisherid)
Publisher(publisherid, code, name)
Write(paperid, authorid)
Edit(editorid, procid)

balance of suppliers for each “yellow tomato” part, whereas SQAK returns the maximum account balance among all the suppliers that supply a “yellow tomato”. Note that our approach can also generate query patterns to compute aggregates without distinguishing objects with the same value.

Queries $T5$ and $T6$ show that by examining the relationships and their participating objects, our approach is able to detect duplicate objects in relationships and generate SQL statements that compute the aggregates correctly. For query $T5$, our approach returns 4 for the number of suppliers that supply “Indian black chocolate”. SQAK counts the same suppliers multiple times for different orders and returns 22, a value that is way above the actual number. Similarly for $T6$, our approach detects the duplicates of suppliers for different orders, and returns the correct number of parts supplied by each supplier, while SQAK returns incorrect answers.

Queries $T7$ and $T8$ demonstrate that our approach can answer aggregate queries that SQAK does not handle. Query $T7$ requires an SQL statement that contains 2 aggregate functions in the SELECT clause. However, SQAK restricts that the SELECT clause of a generated SQL statement specifies exactly one aggregate function. Query $T8$ requires an SQL statement to join 2 *Part* relations, but SQAK does not generate SQL statements that contain self joins of relations.

6.1.2 Results for ACMDL Database

Table 6 shows the answers and explanations for the queries on the ACMDL database. Query $A1$ is relatively straightforward, and both our approach and SQAK return the correct answer. For $A2$, SQAK also gives the correct answer because the term `SIGMOD` matches a proceeding acronym and there is no proceedings with the same acronym.

However, for queries $A3$ and $A4$, there are 61 editors with name `Smith` and 36 authors with name `Gill` in the database. Since SQAK does not distinguish the editors and authors with the same name, it returns incorrect number of proceedings and the most recent date of papers respectively.

Similarly, for query $A5$, our approach returns 6 answers while SQAK only returns 4 answers, as it mixes some papers with the same title.

Query $A6$ involves 2 aggregate functions. Queries $A6$ and $A7$ require self joins of two *Author* relations and two *Editor* relations respectively. SQAK is unable to process these queries, while our approach returns the correct answers.

Table 3: Queries for TPCB database

#	Query	Description
T1	order AVG amount	Find the average amount of orders
T2	MAX COUNT order GROUPBY nation	Find the maximum number of orders among nations
T3	COUNT order “royal olive”	Find the number of orders that contains the “royal olive”
T4	supplier MAX acctbal “yellow tomato”	Find the maximum balance of suppliers that supply the “yellow tomato”
T5	COUNT supplier “Indian black chocolate”	Find the number of suppliers for “Indian black chocolate”
T6	COUNT part GROUPBY supplier	Find the number of parts supplied by each supplier
T7	COUNT order SUM amount GROUPBY mktsegment	Find the number of orders and their total amount for each market segment
T8	COUNT supplier “pink rose” “white rose”	Find the number of suppliers for “pink rose” and “white rose”

Table 4: Queries for ACMDL database

#	Query	Description
A1	proceeding AVG pages	Find the average pages of proceedings
A2	COUNT paper GROUPBY proceeding SIGMOD	Find the number of papers in each ‘SIGMOD’ proceeding
A3	COUNT proceeding editor Smith	Find the number of proceedings edited by ‘Smith’
A4	paper MAX date Gill	Find the date of the latest papers written by ‘Gill’
A5	COUNT author “database tuning”	Find the number of authors for each “database tuning” paper
A6	COUNT paper MAX date IEEE	Find the number of papers published by ‘IEEE’ and most recent date
A7	COUNT paper author John Mary	Find the number of papers co-authored by ‘John’ and ‘Mary’
A8	COUNT editor SIGIR CIKM	Find the number of editors that edit proceedings ‘SIGIR’ and ‘CIKM’

6.1.3 Queries on Unnormalized Databases

Next, we denormalize the ACMDL and TPCB databases, and obtain the unnormalized database schemas in Table 7. We use the queries in Tables 3 and 4 on the unnormalized databases and compare the results returned by SQAK and our approach.

Tables 8 and 9 show that our approach continues to return correct answers to the queries. In contrast, SQAK either returns incorrect answers or does not handle the queries. For queries T1 and T2, SQAK returns the values 1.78×10^5 and 26485 respectively because the information of orders are duplicated in the unnormalized relation *Ordering*. Similarly, SQAK returns the answer 637 for A1, and 2000, 408, 14858, etc. (totally 36 answers) for A2, both of which are incorrect as the information of proceedings and papers are duplicated in the unnormalized relations *EditorProceeding* and *PaperAuthor*. Note that these queries are answered correctly by SQAK when the database is normalized.

For queries T3 to T6 and queries A3 to A5, SQAK returns the incorrect answers for the same reason as discussed in Section 6.1.1 and Section 6.1.2.

This set of experiments clearly demonstrate that the ORA semantics are important to distinguish the various interpretations of keyword queries so that the generated SQL statements will compute statistical information correctly.

6.2 Efficiency Experiments

Finally, we compare the time taken by our approach and SQAK to generate SQL statements. Figure 11 shows the results for TPCB and ACMDL queries in Tables 3 and 4.

We observe that our approach is slightly slower than SQAK for most of the queries. This is because SQAK does not analyze the interpretations of keyword queries but only finds SQNs containing all the query terms. It also does not distinguish objects with the same attribute value or detect the duplicate objects in relationships. Besides, it does not consider the duplications arising from unnormalized relations.

Take query A7 for example. We first parse this query into basic terms (paper, author, John, Mary) and operators (COUNT). Then, we generate a query pattern with one Paper

Table 7: Unnormalized database schemas

TPCB'
Ordering(partkey, supkey, orderkey, pname, type, size, retailprice, sname, nationkey, regionkey, acctbal, custkey, amount, date, priority, quantity)
Customer(custkey, cname, nationkey, regionkey, mktsegment)
Nation(nationkey, nname)
Region(regionkey, rname)
ACMDL'
PaperAuthor(paperid, authorid, procid, date, title, fname, lname)
EditorProceeding(editorid, procid, fname, lname, acronym, title, date, pages, publisherid)
Publisher(publisherid, code, name)

node, two Write nodes and two Author nodes. We annotate the Paper node with the Count operator, and distinguish the authors called John and the authors called Mary respectively. Finally, we detect if information of paper and author objects are duplicated in write relationships, and translate the patterns into SQL statements. In contrast, SQAK does not handle the query because both the terms John and Mary match the values of some tuples in the Author relation.

As the SQL execution time dominates the overall processing time (in seconds), we see that the extra time (in ms) required by our approach to interpret the keyword queries and detect the duplicates is a good tradeoff and important to retrieve correct answers from the databases.

7. RELATED WORK

Existing works on keyword search in relational databases can be classified into data graph approach and schema graph approach. In data graph approach, the relational database is modeled as a graph where each node represents a tuple and each edge represents a foreign key-key reference. BANKS [8] defines an answer to a keyword query as a Steiner tree that contains all the keywords, and proposes a backward expansion search to find the Steiner trees. [9] uses bidirectional

Table 5: Answers of queries for normalized TPCB database

#	SQAK		Our Proposed Approach	
	Answer	Explanation	Answer	Explanation
T1	AVG amount: 1.42×10^5	average amount of orders	AVG amount: 1.42×10^5	average amount of orders
T2	MAX COUNT order: 6568	maximum number of orders among nations	MAX COUNT order: 6568	maximum number of orders among nations
T3	1 answer: 229	incorrect answer: mix all “royal olive” parts	8 answers: 23, 22, 29, 27, 33, 35, 33, 27	number of orders for each “royal olive” part
T4	1 answer: 9844.00	incorrect answer: mix all “yellow tomato” parts	13 answers: 6361.20, 9538.15, ..., 7916.56	maximum account balance of suppliers for each “yellow tomato” part
T5	COUNT supplier: 22	incorrect answer: same suppliers are counted multiple times for various orders	COUNT supplier: 4	number of suppliers that supply “Indian black chocolate”
T6	1000 answers: 593, 571, 595, 606, ...	incorrect answers: same parts are counted multiple times for various orders	1000 answers: 80, 80, 79, 80, ...	number of parts supplied for each supplier
T7	N.A.	do not handle more than one aggregate	5 answers: $\langle 2.99 \times 10^4, 4.26 \times 10^9 \rangle$, ..., $\langle 3.03 \times 10^4, 4.33 \times 10^9 \rangle$	one answer for each market segment
T8	N.A.	do not handle self joins of relations	3 answers: 1, 1, 1	number of suppliers that supply a particular “pink rose” and a particular “white rose”

expansion to reduce the search space. [4] employs dynamic programming to identify the top-k minimal group Steiner trees. [12] finds a subgraph that contains all the keywords within a given distance to be a query answer, and captures more information than a Steiner tree.

In schema graph approach, the database schema is modeled as a graph where each node represents a relation and each edge represents a foreign key - key constraint. DISCOVER [7] proposes a breadth-first traverse on the schema graph to generate a set of SQL statements. Each SQL joins

Figure 11: Comparison of the time taken by our approach and SQAk to generate SQL statements

a minimal number of relations and outputs tuples that contain all the keywords. [6] and [10] relax the requirement that output tuples should contain all the query keywords, and develop top-k keyword query techniques to improve efficiency of [7]. [1] exploits the relative positions of keywords in a query and auxiliary external knowledge to generate SQL statements that satisfy users' search intention.

The above works only examine tuples that contain query keywords and try to link them by foreign key-key references. [17] studies the problem of aggregate keyword search on a universal relation. Given a keyword query, it finds a set of tuples that are grouped by a minimal number of attributes and contain all the keywords. [11] classifies query keywords into dimensional and general keywords, and computes subgraphs that contain all dimensional keywords and some general keywords. These subgraphs are grouped based on dimensional keywords to compute the statistical information of the subgraphs. However, none of these works can answer queries involving aggregate functions and GROUPBY.

SQAk [13] generates a set of SQL statements from a keyword query containing reserved keywords to indicate the aggregate functions in SQL statements. But, it does not consider the ORA semantics, and thus returns incorrect answers as we have highlighted. Moreover, SQAk cannot handle queries when relations in the database are unnormalized.

8. CONCLUSION

In this paper, we have studied the problem of answering keyword queries involving aggregates and GROUPBY on relational databases. Existing work does not consider the ORA semantics, and thus fails to distinguish objects with the same attribute value and detect duplications of objects in relationships. This leads to incorrect computation of aggregate queries. To avoid these problems, we utilize the ORM schema graph to capture the ORA semantics, and propose a semantic approach to answer aggregate queries. Given an aggregate query, we generate a set of annotated query patterns to represent various interpretations of the query. Based on these patterns, we distinguish objects with the same attribute value and detect duplications of objects in relationships. The top-k ranked patterns are translated into SQL statements which apply aggregate functions to compute the statistical information correctly. Further, we develop a mechanism to detect duplications arising from unnormalized relations, and extend our approach to handle aggregate queries on unnormalized databases. Experimental results demonstrate that our approach returns correct answers to aggregate queries both on normalized and unnormalized databases.

ABSTRACT

The detection of communities in social networks is a challenging task. A rigorous way to model communities considers maximal cliques, that is, maximal subgraphs in which each pair of nodes is connected by an edge. State-of-the-art strategies for finding maximal cliques in very large networks decompose the network in blocks and then perform a distributed computation. These approaches exhibit a trade-off between efficiency and completeness: decreasing the size of the blocks has been shown to improve efficiency but some cliques may remain undetected since high-degree nodes, also called hubs, may not fit with all their neighborhood into a small block. In this paper, we present a distributed approach that, by suitably handling hub nodes, is able to detect maximal cliques in large networks meeting both completeness and efficiency. The approach relies on a two-level decomposition process. The first level aims at recursively identifying and isolating tractable portions of the network. The second level further decomposes the tractable portions into small blocks. We demonstrate that this process is able to correctly detect all maximal cliques, provided that the sparsity of the network is bounded, as it is the case of real-world social networks. An extensive campaign of experiments confirms the effectiveness, efficiency, and scalability of our solution and shows that, if hub nodes were neglected, significant cliques would be undetected.

Community detection, maximal clique enumeration, scale-free networks

1. INTRODUCTION

The detection of groups of densely connected nodes, usually called communities, is used to reveal fundamental properties of networks in a variety of domains such as sociology, bibliography, and biology [13, 18, 29]. A rigorous way to model communities considers maximal cliques, that is, maximal subgraphs in which any pair of nodes is connected by an edge. Maximal clique enumeration (MCE) is a paradigmatic problem in computer science and, due to its known complexity, several solutions have been proposed to deal with real-world scenarios [6, 14, 16, 33, 34].

When very large networks are involved, state-of-the-art strategies consist of decomposing the network into blocks that are independently processed in a distributed and parallel environment [8, 10, 14, 20, 31, 36, 38]. A crucial aspect of this approach is the choice of the size m of the blocks. Clearly, m is bounded by the dimension of the memory, but it has been shown that artificially reducing m to values as low as 1/100 or 1/1000 of the available memory results in a more efficient computation [8, 9, 10]. On the other hand, if the size of the blocks is too small, the effectiveness of the approach is compromised. In fact, consider a node n such that the graph induced by its neighborhood does not fit into a block. We call such a node *hub*. In any block of the decomposition a portion of the neighborhood of n will be necessarily omitted and, consequently, some maximal cliques involving n may remain undetected and some non-maximal cliques could be erroneously found.

Hence, while fixing the size of the blocks, state-of-the-art decomposition approaches also need to find a trade-off between efficiency and effectiveness. Even if efficiency is not an issue, effectiveness can be jeopardized since real-world social networks often contain nodes whose degree (i.e., the number of incident edges) is so high that their neighborhood does not fit into main memory altogether.

Actually, high degree nodes are connatural in *scale-free networks*, where the degree distribution of the nodes follows a power law. This property implies that the number of nodes with h connections to other nodes decreases exponentially as h increases and that the set of nodes with arbitrary high degree is not empty [2]. Several works in literature show that social networks, such as Facebook and Twitter, are scale-free [12, 35]. It has also been shown that scale-freeness is exhibited whenever the network has a growth mechanism based on preferential attachment [3, 11], that is, when new connections are distributed among nodes according to how many connections they already have. Hence, as social networks grow, this property is expected to be exacerbated.

In this paper, we address these limitations by proposing an approach to the problem of maximal clique enumeration in very large social networks that meets both the requirements of completeness and efficiency. The approach leverages on sparsity, another property of real-world networks, which basically means that the network can have very dense areas but, overall, nodes and edges are of the same order of magnitude.

Our solution is based on a two-level decomposition of the network. The first-level decomposition aims at recursively identifying and isolating tractable portions involving non-hub nodes only. Intuitively, this operation allows us to “brake” hub nodes by progressively decreasing their degree. The second-level decomposition suitably splits tractable portions of the network into small blocks that can be handled separately. Within a block, we then select the most promising state-of-the-art algorithm for enumerating its maximal cliques. A suitable procedure allows us to recognize and filter out those that are not maximal for the overall network. We formally show that this process is able to correctly detect *all* maximal cliques, provided that the sparsity of the network is bounded, as it is the case of real-world social networks.

We have performed a large number of experiments over data from real-world social networks showing that our approach is effective, efficient, and scalable. The experimentation confirms that in order to have an efficient computation it is convenient to choose a relatively small size of the blocks, which further increases the number of hub nodes. The experiments also confirm that, if hub nodes were neglected, significant cliques would remain undetected.

Summarizing, the contributions of this paper are the following.

- We propose a distributed approach to maximal clique enumeration in large social networks based on a novel decomposition strategy that, by suitably handling high-degree nodes, is able to progressively identify and isolate tractable portions of the network;
- We formally prove the correctness and the completeness of the approach;
- We provide experimental evidence of the efficiency and scalability of our solution and show that, if high-degree nodes were neglected, significant cliques would be undetected.

The rest of the paper is organized as follows. In Section 2 we provide a general overview of our technique. Section 3 describes in depth the two-level decomposition algorithm, Section 4 describes the computation of the maximal clique on a single block of the decomposition, and Section 5 provides the theoretical basis for the whole approach. In Section 6 we illustrate our campaign of experiments. Section 7 surveys the related work and Section 8 contains our conclusions.

2. OVERVIEW AND INTUITION

Our approach is based on a decomposition of the input network in smaller subgraphs called blocks that can partially overlap with each other. As we have discussed in the Introduction, this requires a careful choice of the size of the blocks, depending on hardware limitations and performance

Figure 1: Feasible nodes (white) and hub nodes (red) when $m = 5$.

issues. Whichever the choice, let m be the maximum number of nodes that can fit in a block. The value of m identifies two types of nodes in the network: (i) the set N_h of *hub nodes* having degree greater or equal than m (i.e., those nodes that would not fit into a block with all their neighbors) and (ii) the set N_f of *feasible nodes* having degree less than m .

Consider, for example, the network in Figure 1 and suppose $m = 5$. The set N_h consists of the red-coloured nodes D, S, and E of degree 7, 5, and 5 respectively, whereas N_f consists of the remaining white nodes.

Now, let C_f be the set of all maximal cliques of G involving at least one node in N_f and let C_h be the set of all maximal cliques in the network G_h induced¹ by the nodes in N_h . For example, in the network in Figure 1 we have that C_f includes the cliques $\{A, J, H\}$ and $\{H, F, D\}$, as they both involve feasible nodes, while C_h includes the clique $\{D, S, E\}$, since G_h consists only of the nodes D, S, E and of the edges between them.

Our approach is based on the intuition that the set of all maximal cliques of the network G can be obtained from C_f and C_h alone. This is confirmed by Lemma 1 in Section 5, which establishes that the set of the maximal cliques of G is the union of C_f and the set C'_h obtained by filtering out from C_h any clique that is contained into a clique of C_f .

This result suggests that if we process separately the nodes in N_f and the nodes in N_h , no clique is left out. We then obtain an effective decomposition strategy which is also efficient since the neighbors of a feasible node fit into a block of size m by definition, while the degree of the nodes in the induced graph G_h is strongly reduced since G_h only involves a limited number of nodes in scale free networks. For instance, in the network of Figure 1, G_h is the cycle $\{D, S, E\}$ and its maximum degree is two.

Regarding the computation of the cliques in C_f and C_h we proceed as follows.

C_f : As in [10], we compute a suitable partition of N_f and add to each set S of the partition the neighborhood in G of the nodes in S . The obtained sets of nodes, together with the edges between them, form the blocks of the decomposition. Observe that a node (including

¹We recall that the subgraph of $G = (N, E)$ induced by a set of nodes $N' \subseteq N$ is the restriction of G to the nodes in N' and the edges between them.

the hub ones) may be included into several blocks as a neighbor node, together with a subset of its edges. Differently from [10], we allow for blocks of heterogeneous size and high connectivity that can be processed independently in an efficient way. Then, taking advantage of a decision tree, we apply on each block the most promising MCE algorithm based on the block characteristics. For instance, if the block is sparse, we find the maximal cliques with the algorithm in [17], while if the block is dense we adopt the algorithm described in [34].

C_h : We apply the whole approach recursively to G_h by partitioning its nodes N_h into two sets N'_f and N'_h of feasible and hub nodes, respectively. This is possible since the degree of the nodes in N_h is strongly reduced. The recursion produces a sequence of sets N'_f , N''_f , N'''_f , ... of decreasing size until there are no more hub nodes remaining.

In Section 5 we prove that, under the hypothesis that the input graph is sparse enough, this recursive process converges, in the sense that it ends with a bipartition involving only tractable nodes. In addition, in Section 6, we report that in all our experiments on real-world data sets the process needed at most a few recursive steps.

Summarizing, our approach consists of the following.

1. **First level decomposition:** we identify the set N_f of *feasible* nodes of G , whose degree is less than m , and the set N_h of *hub* nodes of G , whose degree is greater or equal than m .
2. **Recursive call:** if N_h is not empty, we build the subgraph G_h of G induced by the nodes in N_h and apply recursively the whole process to G_h .
3. **Second level decomposition:** given a set of feasible nodes N_f we compute a set of blocks by partitioning N_f and by adding to each node of a block its neighbors.
4. **Block analysis:** we apply a suitable MCE algorithm to each block generated by the second level decomposition to compute all its maximal cliques. The MCE algorithm is chosen from a collection of alternatives, taken from the literature, based on the properties of the block, as described in Section 4.
5. **Filtering:** the output is obtained by taking the union of the maximal cliques computed in step 4 and those computed in step 2, filtering out redundant cliques.

In the following sections we will describe in more detail the various steps of this strategy.

3. NETWORK DECOMPOSITION

Algorithm 1 (FIND-MAX-CLIQUEs) describes our recursive procedure for computing maximal cliques. The CUT procedure (line 1) performs the first-level decomposition while the BLOCKS procedure (line 2) performs the second-level decomposition. In this section we describe in detail both of them.

Algorithm BLOCK-ANALYSIS (line 5) is discussed in Section 4. Procedure **induced** (line 6) accepts as input a graph G and a subset N_h of its nodes and computes the subgraph of G induced by N_h . Procedure **filter** (line 7) accepts as input two sets C_h and C_f of cliques and outputs all cliques in C_h that are not contained into some clique of C_f .

Algorithm 1: FIND-MAX-CLIQUEs: Overall algorithm

Input : A graph $G = \langle N, E \rangle$ and a block size m .

Output: The set C of the maximal cliques of G .

```

1  $\langle N_f, N_h \rangle \leftarrow \text{CUT}(G, m);$  /* 1st level decomp. */
2  $\mathcal{B} \leftarrow \text{BLOCKS}(G, N_f, m);$  /* 2nd level decomp. */
3  $C_f \leftarrow \emptyset;$ 
4 foreach  $b \in \mathcal{B}$  do
5    $C_f \leftarrow C_f \cup \text{BLOCK-ANALYSIS}(b);$ 
6  $C_h \leftarrow \text{FIND-MAX-CLIQUEs}(\text{induced}(G, N_h), m);$ 
7  $C'_h \leftarrow \text{filter}(C_h, C_f);$ 
8 return  $C_f \cup C'_h;$ 

```

3.1 First level decomposition

Algorithm 2 describes the CUT procedure that is responsible of identifying the set N_f of feasible nodes and the set N_h of hub nodes. This is done by means of the procedure **isfeasible** (also called by procedure **BLOCKS**) that takes as input a set of nodes, the graph G and the maximum block size m and checks whether the union of the given nodes and all their neighborhoods in G has less than m elements. The set N_h of hub nodes is simply obtained, at line 5, as the difference between the nodes of G and N_f .

Algorithm 2: CUT: First-level decomposition

Input : A graph $G = \langle N, E \rangle$ and a block size m .

Output: The sets N_f and N_h of feasible and hub nodes of G , respectively.

```

1  $N_f \leftarrow \emptyset;$ 
2 foreach  $n \in N$  do
3   if isfeasible( $\{n\}, G, m$ ) then
4      $N_f \leftarrow N_f \cup \{n\};$ 
5  $N_h \leftarrow N - N_f;$ 
6 return  $\langle N_f, N_h \rangle;$ 

```

3.2 Second level decomposition

Algorithm 3 describes the BLOCKS procedure, responsible of decomposing the input graph G into tractable blocks of maximum size m . The input graph G is assumed to have maximum degree $m - 1$. Here, we model blocks similarly to [10] but allow for blocks of heterogeneous sizes and leverage the adjacency of the nodes to put dense subgraphs into the same block. Hence, this step, in addition to distributing the computational load into tasks that could be accomplished separately in a distributed environment, also pre-processes the input producing internally homogeneous and compact chunks.

Blocks are defined sequentially in a greedy way. Each block will have *kernel* nodes, *border* nodes, and *visited* nodes. Each node of N_f is kernel node in exactly one block (i.e., kernel nodes form a partition of N_f). All the nodes of G that are adjacent to at least one kernel node of a block B and that are not kernel nodes of B are divided into border nodes and visited nodes of B , where visited nodes are those nodes that have been already used as kernel nodes for some previously defined block. The block is completed with all the edges among its nodes, irrespectively of the type.

For instance, consider again the network in Figure 1.

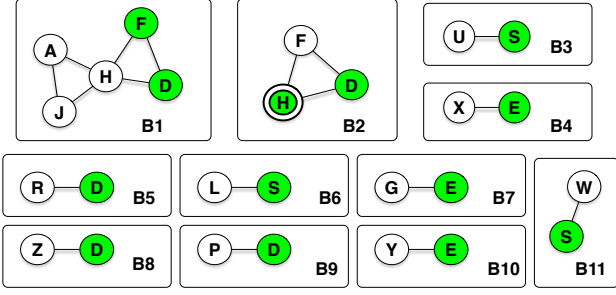

Figure 2: An example of graph decomposition obtained by focusing on the feasible nodes of the network of Figure 1.

Nodes D, E, and S are identified as hub nodes by procedure **FIND-MAX-CLIQUE**s and will be processed in a subsequent recursive call of the same procedure. Figure 2 shows a possible decomposition of the network in eleven blocks obtained by focusing on the remaining non-hub nodes. In the figure kernel nodes are white, border nodes are green and visited nodes are double-marked. Note that all feasible nodes (white-filled in Figure 1) occur in exactly one block as kernel nodes (white-filled in Figure 2). Also, observe that each block of Figure 2 includes all the neighborhood of the kernel nodes. However, the hub nodes (D, E, and S) never occur as kernel nodes in any block. Instead, their neighborhood has been distributed among the various blocks. Finally, note that every maximal clique occurs in at least one block: this is an important property that allows us to independently process each block. If a maximal clique occurs in more than one block, only the occurrence without visited nodes will be considered. This is the case, for instance, for the maximal clique $\{H, F, D\}$ that is detected both when processing B1 and when processing B2, but is discarded in the latter case since it contains a visited node.

We start to build a block B by picking a node n from N_f (line 4 of Algorithm 3) and adding it to the set K of kernel nodes of B (line 8). We then build: (i) the set V of visited nodes (line 9), composed of neighbors of nodes in K that are already used as kernel nodes in a previously defined block (we maintain these latter nodes in \bar{K} , which is updated at line 7), and (ii) the set H of border nodes (line 10), composed of neighbors of K that are not yet visited. Then we proceed by selecting one node of N_f that is a border node of B and transforming it into a kernel node of B (line 10). In order to produce blocks that correspond to dense graphs, we order the candidate border nodes based on the number of their adjacency with kernel nodes, and we stop either if we exceed the limit m by adding further nodes (line 5) or if all candidate border nodes have a number of adjacency with kernel nodes below a specified threshold.

4. MAXIMAL CLIQUES COMPUTATION

In order to find all maximal cliques in a block of the decomposition, we rely on a framework that leverages on a collection of algorithms taken from the literature with the goal of improving the overall performance of the computation.

The MCE problem has been subject of extensive study since the early 70's [6, 8, 10, 17, 21, 23, 34]. None of the

Algorithm 3: BLOCKS: Second-level decomposition

Input : A graph $G = \langle N, E \rangle$, a set N_f of feasible nodes, and a block size m .

Output: A set of blocks \mathcal{B} .

```

1  $\bar{K} \leftarrow \emptyset; \mathcal{B} \leftarrow \emptyset;$ 
2 while  $N_f \neq \emptyset$  do
3    $K, H, V \leftarrow \emptyset;$ 
4    $n \leftarrow \text{select}(N_f);$ 
5   while  $\text{isfeasible}(K \cup \{n\}, G, m)$  do
6      $N_f \leftarrow N_f - \{n\};$ 
7      $\bar{K} \leftarrow \bar{K} \cup \{n\};$ 
8      $K \leftarrow K \cup \{n\};$ 
9      $V \leftarrow N(n) \cap \bar{K};$ 
10     $H \leftarrow N(n) - V;$ 
11     $n \leftarrow \text{select}(N_f \cap H);$ 
12   $\mathcal{B} \leftarrow \mathcal{B} \cup \text{induced}(G, K \cup H \cup V);$ 
13 return  $\mathcal{B};$ 
```

available algorithms outperforms the others in every possible instance of the problem. However, some approaches tend to excel on graphs having specific properties. For example Eppstein *et al.* [17] propose an algorithm that runs in near-optimal time on graphs having small degeneracy². On the contrary, this algorithm does not perform well on dense graphs where the degeneracy tends to be higher. On these graphs, the algorithm proposed by Tomita *et al.* [34] tends to be more efficient.

Our approach attempts at predicting, for each block, the *best-fit* among the available MCE algorithms, that is the one that achieves the best performance on it. The intuition behind this approach is that large heterogeneous networks yield blocks with very different characteristics, so that any algorithm would be suboptimal in a non-negligible portion of the blocks.

In order to efficiently predict the best-fit algorithm for a block, we first identified a set of easy-to-compute parameters to describe the block properties. Second, we selected a set of supporting data-structure and state-of-the-art MCE algorithms. Third, we measured the performance of each combination of data-structure/algorithm on a collection of heterogeneous graphs. Finally, we used the results as a training set to produce a decision tree aimed at selecting the best combination for a given block.

The parameters we used to classify blocks are the following: (a) number of nodes; (b) number of edges; (c) density; (d) degeneracy; and (e) the maximum value d^* for which the graph has at least d^* nodes with degree greater or equal than d^* . Parameter d^* can be computed in linear time and, intuitively, provides an estimate of the size of the densest portion of the graph, which we expect to dominate the performance of a search algorithm.

We considered three different data structures to represent the graph: adjacency matrices, bitsets, and adjacency lists (the latter including the inverted-table structure described in [17]).

As for the MCE algorithms, we implemented the following:

- **BKPivot**: one of the original algorithms proposed by

²See Section 5 for a formal definition of degeneracy.

Algorithm	Matrix	Lists	BitSets
BKPivot [6]	7	0	2
Tomita [34]	5	3	12
Eppstein [17]	0	2	0
XPivot	7	12	0

Table 1: Performance of the MCE algorithms.

Bron and Kerbosch [6]. It uses a pivot to avoid redundant recursive calls. The node of highest degree in the candidate set P is chosen as the pivot.

- **Tomita**: a variation of BKPivot by Tomita *et al.* [34]. It uses as pivot the node u that maximizes the size of $N(u) \cap P$, where $N(u)$ denotes the neighborhood of u .
- **Eppstein**: the algorithm by Eppstein and Strash [17]. It is based on a degeneracy ordering of the nodes to achieve a better complexity on sparse graphs.
- **XPivot**: a variation of BKPivot proposed by us. Like Tomita, it chooses the node that maximizes the size of $N(u) \cup P$, but the node u is chosen from the set of already visited nodes.

In Table 1 we show a performance comparison of the data-structure/algorithm combinations described above on a collection of 50 graphs, both synthetic (generated according to the models of Erdős-Renyi, Barabási-Albert and Watts-Strogatz models [2]) and real-world (taken from the SNAP project [22]). In particular, the table shows how many times a specific combination resulted the best performing among all the alternatives. It is apparent that no algorithm outperforms all the others in all cases.

Table 2 shows the maximum and minimum values of the adopted parameters in the collection and confirms that the graphs have heterogeneous properties.

Metric	Min value	Max value
nodes	50	685230
edges	199	6649470
density	0.00027	0.89
degeneracy	10	266
d^*	15	713

Table 2: Ranges of adopted parameters for the chosen graphs.

We divided the graph collection in training and testing set with an 80/20 ratio. We then used the training set and the above parameters to generate the decision tree in Figure 3, launching the *recursive partitioning* algorithm in [32]. Each internal node of the tree contains a predicate on the parameters and has two children, associated with the predicate being **true** or **false** on the current block. Each leaf of the decision tree contains a data-structure/algorithm combination. Traversing the tree from the root to a leaf according to the values of the predicates yields the data-structure/algorithm combination that is the best-fit for the block.

The testing set was used to evaluate the effectiveness of this approach. Figure 4 shows the total time taken by our approach to process the testing set and the five best performing combinations. Note that the use of the decision

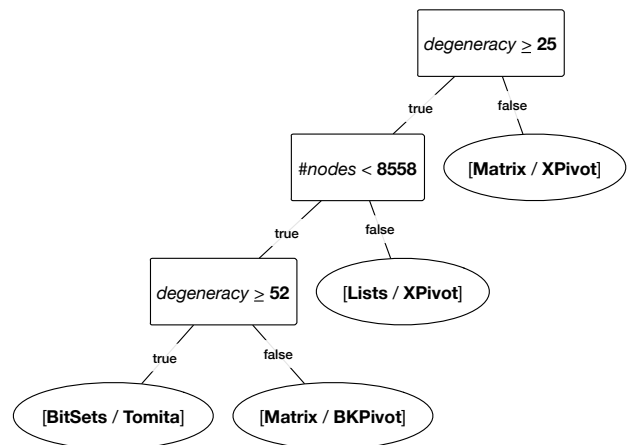

Figure 3: The decision tree for selecting the most suitable MCE algorithm.

Figure 4: Times to compute cliques with or without a decision tree.

tree achieves better performance than any other algorithm taken singularly.

Algorithm 4 describes in detail the BLOCK-ANALYSIS procedure that computes all maximal cliques of the block given as input.

First, a suitable MCE procedure is identified by using the decision tree described above (line 1).

As described in Section 3.2, the purpose of Algorithm 4 is to find all maximal cliques that have at least one node in K , but no node in the set V of visited nodes of the input block. In line 3 we initialize \bar{V} with V . For each node k in the set K of kernel nodes of the input block, Algorithm MCE(k, P, \bar{V}) enumerates all maximal cliques that contain k and no node in \bar{V} as long as all the neighbors of k are in $P \cup \bar{V}$. One can observe that all neighbors of k are either in the set H of border nodes of the input block, or in K or in \bar{V} . Therefore, procedure BLOCK-ANALYSIS detects all maximal cliques containing a node of K and no node in V . Finally, after k is visited, it is added to \bar{V} since all cliques containing k have been found.

5. THEORETICAL BASIS

In this section we prove under what conditions our approach is correct and complete. Namely, Lemma 1 proves

Algorithm 4: BLOCK-ANALYSIS: Clique detection

Input : A block $\langle N = K \cup H \cup V, E \rangle$.
Output: The maximal cliques \mathcal{C} of B that have at least one node in K , but no node in V .

```
1 MCE  $\leftarrow$  bestfit( $B$ );  
2  $P \leftarrow K \cup H$ ;  
3  $\bar{V} \leftarrow V$ ;  
4 foreach  $k \in K$  do  
5    $N_k \leftarrow N(k) \cap P$ ;  
6    $\mathcal{C} \leftarrow \mathcal{C} \cup \text{MCE}(k, P \cap N_k, \bar{V} \cap N_k)$ ;  
7    $P \leftarrow P - \{k\}$ ;  
8    $\bar{V} \leftarrow \bar{V} \cup \{k\}$ ;  
9 return  $\mathcal{C}$ ;
```

that **FIND-MAX-CLIQUE** (Algorithm 1 in Section 3) actually computes all maximal cliques of the input network. Theorem 1, instead, shows that **FIND-MAX-CLIQUE** terminates its recursive calls whenever the input network is sparse.

Sparsity is a well known property of social networks and can be formally measured in terms of their low *degeneracy* [35]. The degeneracy of a network, also called *coreness*, is the highest value d for which the network contains a d -core³. Hence, a network with a low degeneracy is inherently sparse. The degeneracy of a network can be easily computed, even in a distributed environment (see, e.g., [4]), and it is usually much lower than the maximum degree of the network. Indeed, real-world social networks have low degeneracy [35].

LEMMA 1. *Let N_1 and N_2 be any bipartition of the nodes of a graph G . Let C_1 be the set of the maximal cliques of G containing at least one node of N_1 and let C_2 be the set of maximal cliques of the subgraph of G induced by the nodes in N_2 . The set of the maximal cliques of G is the union of C_1 and the set C'_2 obtained by filtering out from C_2 any clique that is contained into a clique of C_1 .*

PROOF. Let K be a maximal clique of the network. We show that K is in $C_1 \cup C'_2$. We have two cases: (i) at least one node of K is in N_1 or (ii) all nodes of K are in N_2 . In the first case K belongs to C_1 and, hence, it is also in the union of C_1 and C'_2 . In the second case K is in C_2 and, since by hypothesis K is maximal, it is also in C'_2 , and hence in the union of C_1 and C'_2 .

Conversely, let K be a clique in the union of C_1 and C'_2 . We show that K is a maximal clique. Suppose, for a contradiction, that K' is a clique containing K and having a vertex v in addition to the vertices of K . One of the following three cases applies: (a) at least one node of K belongs to N_1 ; (b) all nodes of K belong to N_2 and v also belongs to N_2 ; or (c) all nodes of K belong to N_2 and v belongs to N_1 . In Case (a), both K and K' belong to C_1 , contradicting the hypothesis that C_1 is composed of maximal cliques. In Case (b), both K and K' belong to C_2 , contradicting the hypothesis that C_2 is composed of maximal cliques. Finally, in Case (c), K belongs to C_2 while K' belongs to C_1 . However, since K is contained into K' , K does not belong to C'_2 , contradicting the hypothesis that K belongs to the union of C_1 and C'_2 . \square

³The d -core of a graph is obtained by recursively removing nodes with degree less than d .

Figure 5: The construction for $m = 4$ of graph H_n used to prove Statement 2 of Theorem 1.

The following theorem shows that, if the network is sparse, the recursive algorithm **FIND-MAX-CLIQUE** converges, in the sense that it ends with a bipartition involving only tractable nodes.

THEOREM 1. *Let G be a graph and let G_i , with $i = 1, 2, 3, \dots$ be a sequence of subgraphs of G such that $G_1 = G$ and G_i , for $i > 1$ is the graph induced by the nodes of G_{i-1} of degree greater or equal than m . Let the degeneracy d of G be strictly less than $m + 1$.*

1. *There is a value q such that all G_j , with $j \geq q$, are empty graphs.*
2. *There exists a graph with n nodes for which q is $\Omega(n)$.*

PROOF. Statement 1 is proved by observing that graphs G_i , with $i > 1$, are obtained from G by iteratively removing nodes of degree less or equal than m . For i large enough, such iterative removal coincides with a recursive removal and, hence, leads by definition to the $(m + 1)$ -core of G , which is the empty graph since $d < m + 1$.

Statement 2 is proved by producing a graph H_n with n nodes and whose degeneracy is $d < m + 1$ such that $q \in \Omega(n)$, as follows. Start from H_1 composed of the isolated node v_1 and, for $j = 2, 3, \dots, n$, obtain H_j by adding a node v_j to H_{j-1} . For $j \leq m + 1$ connect v_j to all previously inserted nodes, so that, H_j , with $j \leq m + 1$, is a complete graph on the first j nodes (see Figure 5 where $m = 4$). For $j > m + 1$ connect v_j to the previous m nodes that have lower degree. It is easy to check that:

- (a) v_j has degree m in H_j , for any $j > m + 1$. For example, in Figure 5 node v_6 has degree 4 in H_6 .
- (b) v_{j-1} has degree $m + 1$ in H_j , for any $j > m + 2$. For example, in Figure 5 node v_6 has degree 5 in H_7 .
- (c) v_1, v_2, \dots, v_{j-2} have degree greater than m in H_j , for any $j > m + 3$. For example, in Figure 5 nodes v_1, v_2, \dots, v_6 have degree greater than 4 in H_8 .

Therefore, for $j > m + 3$, the three conditions (a), (b), and (c) hold and the removal of all nodes of degree less or equal than m from H_j only removes v_j , yielding H_{j-1} . This implies that: (i) recursively removing all nodes of degree less or equal than m from H_n yields the empty graph, i.e., the degeneracy of H_n is less than $m + 1$ and (ii) $\Omega(n)$ removals are needed to obtain the empty graph from H_n . \square

Network	# of nodes	# of edges	Maximum degree

google+	6,308,731	81,700,035	1,098,000

Table 3: The data sets used in the experimentation.

Theorem 1 proves that, in order to guarantee that all maximal cliques are detected, **FIND-MAX-CLIQUEs** only requires that m is chosen to be greater than $d - 1$, where d is the degeneracy of the network (Section 6 shows how to pick a good value for m). We remark that, although the very special graph described in the proof of Theorem 1 requires $\Omega(n)$ recursive steps, in all our experiments with real-world data sets the process needed at most a few of them (see Section 6).

6. EXPERIMENTAL RESULTS

We implemented our approach for maximal clique enumeration into a C++ system using OpenMPI v1.8 library. This section reports the results of the experimentation of the system.

6.1 Benchmark Environment

We deployed our system on a 10-nodes time-shared cluster, where each machine is equipped with 8 GB DDR3 RAM, 4 CPUs 2.67 GHz Intel Xeon with 4 cores and 8 threads, running Scientific Linux 5.7, with the TORQUE Resource Manager process scheduler. The system is provided with the Lustre file system v2.1. The performance of our system has been measured with respect to data loading (i.e., decomposition), and all maximal cliques computation time (i.e., block analysis).

For our experiments we used some of the largest available social networks (see Table 3) taken from SNAP [22] and from the Koblenz Konect repositories⁴. In particular we considered three portions of the “follower network” of Twitter (labeled **twitter1**, **twitter2** and **twitter3** in Table 3), the friendship network of Facebook enriched with posts to user’s wall (labeled **facebook**), and “circles” data from Google+ (labeled **google+**). All these data sets are scale-free networks and provide a significant number of hub nodes. Figure 6 shows a truncated degree distribution of all considered data sets: as discussed in the Introduction, all networks follow a power law for which most of the nodes (i.e. 91% of the total, on average) provide a degree included in the range $[1, 20]$. Nevertheless, on average, in each data set the amount of possible hub nodes (i.e. they provide the maximum degree) represents the 3% of the total set of nodes.

6.2 Network Decomposition

We distributed the input data set among the ten machines of our cluster: each data set is locally split into files whose records contain triples in the format $\langle n_1, e, n_2 \rangle$, where n_1 and n_2 are the labels of the nodes and e is the label of the edge between them. To speed-up the process we encoded node and edge labels with hashes.

⁴Available at <http://konect.uni-koblenz.de/downloads/\#rdf>

Figure 6: Truncated degree distribution of data sets.

On each data set we ran Algorithm **FIND-MAX-CLIQUEs** three times on each machine and measured the average time used to produce the blocks (including the I/O time). Figure 7 shows for each data set the average time to perform the two-level decomposition with respect to the ratio m/d , where m is the maximum number of nodes in a block and d is the maximum node degree. In the experiment we considered five ratios (i.e. 0.9, 0.7, 0.5, 0.3, and 0.1) obtained by decreasing m . As the block size limit decreases, the number of blocks increases and consequently it increases also the time to perform the decomposition. It also causes the increase of the number of hub nodes as well as the increase of the number of maximal cliques involving hubs (see Section 6.3).

We remark that for $m/d \in \{0.5, 0.9\}$ all data sets required two iterations of the first-level decomposition, while for $m/d \in \{0.1, 0.3\}$ all data sets were decomposed after three iterations. This confirms what formally enunciated in Theorem 1. The results in Figure 7 confirm the feasibility of the approach.

Figure 7: Times to compute the decomposition.

6.3 Clique computation

For evaluating the computation times of our approach we ran Algorithm **BLOCK-ANALYSIS** three times on all blocks and measured the average overall time (including the I/O time). Figure 8 shows the average response time in seconds to compute all maximal cliques with respect to the values 0.9, 0.7, 0.5, 0.3, and 0.1 for m/d . All times refer to a serial pro-

Figure 8: Times to compute all maximal cliques.

cessing (i.e., they do not account for the speed-up due to simultaneous computations on distributed platforms).

Efficiency. Our experiments confirm that the running times benefit from relatively small values of m . The fact that the overall performance is improved when smaller blocks are involved is likely due to the efficiency of the clique detection algorithms on small instances. Hence, it can be argued that the decomposition phase is playing the role of a pre-processing step for the MCE problem, producing blocks that can be regarded as approximate solutions to be refined by an exact MCE algorithm.

For small values of m/d (i.e., 0.3 and 0.1) we have many blocks and the performance of the entire process are affected by an increasing overlap among the neighborhood of each block and an increasing communication overhead among the machines of the cluster. As shown in Figure 8, the value $m/d = 0.5$ is a common “saddle point” for all data sets.

Effectiveness. Figure 9.(a) and Figure 10.(a) show the number of cliques computed with respect to the same five ratios used above and Figure 9.(b) and Figure 10.(b) show the average size of the cliques. In all the figures, white bars denote maximal cliques computed from the blocks built from the feasible nodes, while gray bars refer to maximal cliques computed from the blocks built from the hub nodes. Figure 9.(a) and Figure 10.(a) clearly show the contribution of our approach: in all the experiments we had a non-negligible number of maximal cliques involving hub nodes only, that could be omitted or could induce the erroneous detection of non-maximal cliques if the techniques described in this paper were not adopted. In particular, as the ratio between the block size and the maximum node degree decreases, the portion of maximal cliques involving only hub nodes is significantly increased (i.e. reducing m artificially increases the number of hub nodes).

Figure 9.(b) and Figure 10.(b) focus on the size of the produced cliques. It turns out that the sizes of the cliques involving only hub nodes are comparable with (and, in average, greater than) the sizes of the cliques involving feasible nodes. This is more apparent when the ratio m/d is smaller

(i.e., 0.3 and 0.1). Furthermore, observe that the cliques involving only hub nodes are comparable in size with the biggest cliques contained in the network. Hence, even when the cliques computed on the hub nodes are a small percentage, they are among the most significant when their size is considered.

In order to better estimate how much significant are the maximal cliques composed exclusively of hub nodes, we focused on the 200 largest maximal cliques. Figure 11 shows the percentage of maximal cliques computed on the feasible nodes and the percentage of maximal cliques computed on the hub nodes (with respect to the same five values of m/d used for Figures 9 and 10). The percentage of maximal cliques computed on the hub nodes grows significantly around the value $0.5m/d$. In particular, for values of $m/d \in [0.1, 0.5]$, the percentage of maximal cliques computed on hub nodes is between 20% and 80% for all data sets. This confirms that decreasing the block size for boosting efficiency has a dramatic impact on the number of significant maximal cliques that would be lost if the techniques described in this paper were not adopted.

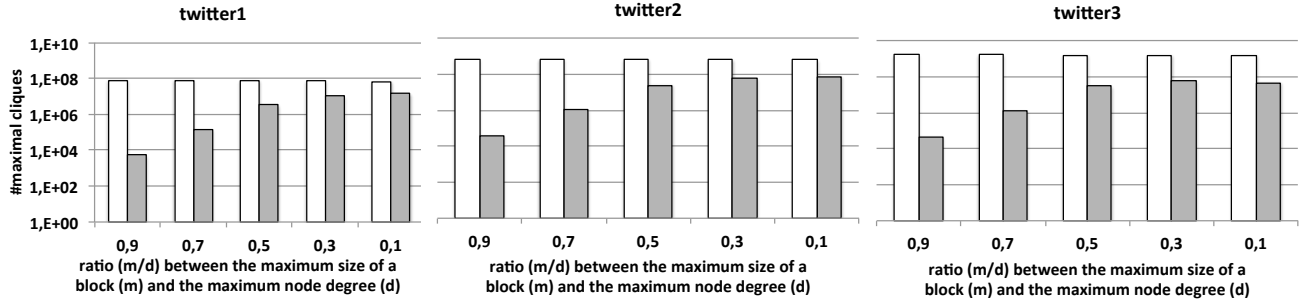

7. RELATED WORK

Despite a long research history, the MCE problem has recently re-emerged as one of the key research topics of graph mining. Due to the NP-completeness of the problem, traditional algorithms for enumerating maximal cliques rely on pruning techniques in order to reduce the search space and speed up the execution [27, 33]. With the increasing dimension of nowadays social networks such algorithms are not satisfactory anymore because the size of the input network often exceeds the available memory.

To address this issue, new approaches have been introduced [8, 10, 30, 36, 38, 7]. They usually rely on a decomposition phase that splits the graph into (partially overlapping) blocks and on distributed computation on the independent blocks to detect all the maximal cliques therein.

ExtMCE [8, 38] is the first algorithm that handles graphs that do not fit into main memory. It starts the search for maximal cliques from a sub-portion of the whole graph, called H^* -graph. However, **ExtMCE** works under the assumption that the H^* -graph fits into main memory, which may be again too restrictive with real-world networks.

The same authors improved their approach introducing the **EmMCE** algorithm [10] that takes advantage of parallelization to reduce I/O overhead and to distribute computation loads. As confirmed also by our experimentation, in [10] it is shown that producing blocks of much smaller size than the available memory yield better time performance. At the same time, though, algorithm **EmMCE** assumes that the neighborhood of each node fits within a block. This clearly poses a trade-off between efficiency and correctness. In fact when the neighborhood of a node does not fit into a single block some of its maximal cliques may be discarded and some non-maximal cliques could be erroneously detected. Furthermore, even if efficiency was not an issue, correctness and completeness are lost whenever the graph has nodes of degree so high that their neighborhood does not fit into main memory. Trying to address this problem in [10] it is suggested to decompose the graph considering nodes in increasing degree order. This results into artificially augmenting the size of a graph fitting into a block, since, when a hub node is chosen as a kernel node, its neighborhood would be

(a) Number of computed cliques

(b) Average number of nodes per clique

Figure 9: The results of the experimentation on twitter1, twitter2, and twitter3 data sets. White bars refer to cliques computed from the feasible nodes while gray bars refer to cliques containing only hub nodes.

largely composed by visited nodes, and edges among visited nodes could be omitted from the block. Nevertheless, all neighbors of a hub node need to be stored into the block as before, and the block size limit still hinder correctness.

Chang *et al.* [7] find all maximal cliques in polynomial delay: cliques are found one after the other and the time-complexity of finding the next clique in the sequence is polynomial. They improve over the previously polynomial-delay fastest algorithm for MCE [24] by using a strategy that partitions the graph into low and high degree nodes.

The authors in [38] focus on the skews of the parallel computation of cliques, since the analysis of few blocks takes far more time than the rest. They also propose algorithms that can incrementally update the maximal cliques when the graph is updated.

Xing *et al.* [36] use a recursive algorithm, called **BMC**, for partitioning the network into blocks. Then, they use an algorithm based on MapReduce to compute the cliques present in each block. Since **BMC** generates blocks having similar size, inter-block cliques are skipped and the approach is not complete. Gregori *et al.* [20] and Rossi *et al.* [30] find the maximal k -cliques and the largest cliques in a parallel way, respectively. These approaches can not be adapted to find all maximal cliques.

Computations over massive networks often take advantage of distributed graph processing systems such as GraphLab/PowerGraph [19] and Pregel/Giraph [25]. They provide: (a) a fault-tolerant infrastructure for processing distributed data; (b) a graph partitioning technique; and (c) an abstract computational model for implementing algorithms. While we could benefit from the infrastructures and abstract models, the partitioning techniques of such systems (point (b) above) are not suitable in the MCE context. They usually use random partitioning (i.e., hash partitioning) which is proven to be the worst possible partitioning for scale-free networks [15]. Instead, as shown in Section 6, we benefit from a decomposition that produces dense chunks of different size.

Maximal Clique Enumeration is especially used for detecting communities in social networks. Several approaches for community detection, rely on a relaxed concept with respect to the enumeration of maximal cliques and consider each subgraph that approximates a clique as a community [29, 39, 28, 1]. In the remaining part of this section we briefly review some of them.

WalkTrap [28] computes random traversals to individuate communities. The heuristic idea of **WalkTrap** is that a random path would likely stay “trapped” inside a subgraph of highly connected nodes. The random path cliques do not give any warranty on the quality of the solutions as, choosing randomly, they might not retrieve a tight community.

There are several approaches that find communities as the subgraphs resulting from the clustering of the edges in the network (see, for example, [1]). They uniquely assign each individual to a cluster. Clearly, this assumption is not suitable for social networks where an individual may belong to multiple communities. To face this aspect, a series of works have been proposed in order to allow overlapping communities (see the survey in [37]).

Differently from all approaches mentioned above, **SCD** [29] employs a parallel strategy to detect the subgraphs that maximize the number of contained triangles, since this measure is indicative of how tight is a community. In [39] it is

introduced the concept of *k-mutual-friend* to find communities and, additionally, it is described a system to browse the communities in a visual manner.

Finally, there are approaches that retrieve communities in terms of *k-plexes*, which are relaxations of cliques in which a node can miss at most k neighbours [5, 26].

8. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented a novel technique for computing all the maximal cliques of an arbitrarily large network in a distributed environment. The approach relies on a two-level decomposition strategy that allows us to achieve efficiency by suitably lowering the size of the blocks without jeopardizing completeness. This is confirmed by a number of theoretical results showing the correctness and completeness of the technique over sparse graphs, a natural property of real-world social networks.

An extensive campaign of experiments conducted over real-world scenarios has shown the efficiency and scalability of our proposal. We have also demonstrated experimentally that, if our technique was not adopted, a significant portion of the most relevant cliques would have been lost.

In the future, we plan to explore the possibility of extending our approach to relaxed definitions of communities, such as k -cliques, k -clubs, k -clans, and k -plexes. We are also interested in studying an incremental version of our approach that takes into account the evolution of the social network.

ABSTRACT

Time series classification is an important problem that has received a great amount of attention by researchers and practitioners in the past two decades. In this work, we propose a novel algorithm for time series classification based on the discovery of class-specific representative patterns. We define representative patterns of a class as a set of subsequences that has the greatest discriminative power to distinguish one class of time series from another. Our approach rests upon two techniques with linear complexity: symbolic discretization of time series, which generalizes the structural patterns, and grammatical inference, which automatically finds recurrent correlated patterns of variable length, producing an initial pool of common patterns shared by many instances in a class. From this pool of candidate patterns, our algorithm selects the most representative patterns that capture the class specificities, and that can be used to effectively discriminate between time series classes. Through an exhaustive experimental evaluation we show that our algorithm is competitive in accuracy and speed with the state-of-the-art classification techniques on the UCR time series repository, robust on shifted data, and demonstrates excellent performance on real-world noisy medical time series.

1. INTRODUCTION

Massive amount of time series data are generated daily in areas as diverse as medicine, astronomy, industry, sciences, and finance, to name just a few. Even with the explosion of interest in time series data mining during the past two decades, and increasing popularity of new emerging topics such as motif discovery, classification of time series still remains one of the most important problems with many real-world applications in diverse disciplines.

While many classification algorithms have been proposed for time series, it has been shown that the nearest neighbor classifier, albeit simple in design, is competitive with the more sophisticated algorithms like SVM [32]. As a result, many existing techniques on time series classification focus on improving the similarity measure, an essential part of the nearest neighbor classifier [4]. Recently, the notion of time series shapelets—time series subsequences that are “maximally representative” of a class—has been proposed. Shapelets generalize the lazy nearest neighbor classifier to an eager, decision-tree-like classifier [36][10], which typically improves the classification speed and interpretability of the results.

In this work, we focus on a similar problem of finding the most representative patterns for the classification task. We call our algorithm RPM (Representative Pattern Mining). The key motivation is that the identification of a small set of distinctive and interpretable patterns of each class allows us to exploit their key characteristics for discriminating against other classes. In addition, we hypothesize that the classification procedure based on a set of highly class-characteristic short patterns will provide high generalization performance under noise and/or translation/rotation, i.e. it shall be robust and shift/rotation invariant.

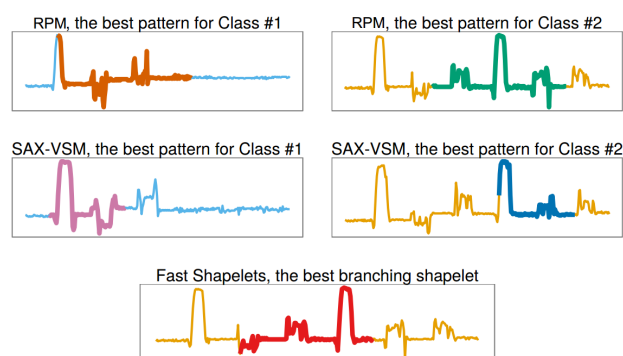

Figure 1: An illustration of the best patterns discovered by rival subsequence-based techniques on Cricket data [20].

Our work is significantly different from existing subsequence-based techniques such as K -shapelet discovery and

classification algorithms. Specifically, one major difference lies in our definition of *representative patterns*. We define representative patterns to be class-specific prototypes, i.e. each class has its own set of representative patterns, whereas in shapelets some classes may share a shapelet. Figure 1 shows the patterns/shapelets identified by different algorithms on the Cricket dataset [20]. Note that SAX-VSM [31] captures visually similar short patterns of the same length in both classes. Fast Shapelets [27] selects a single subsequence to build a classifier. Our algorithm, RPM, selects different patterns that capture the data specificity (characteristic left and right hand movements) for each class.

The methodology employed by our approach is also very different from existing shapelet-based techniques. Contrasting with a decision-tree-based shapelet classification which finds the best splitting shapelet(s) via the exhaustive candidate elimination and explicit distance computation, we rely on the grammar induction (GI) procedure that *automatically* (i.e. by the algorithm’s design) and *without computing any distance explicitly* [17][30] discovers frequent subsequences (motifs) of *variable length*, which we consider as representative pattern candidates. The number of candidates for the exhaustive shapelet search approach is $O(nm^2)$ (n is the number of time series, m is their length) [27], since the algorithm examines all possible subsequences. For our method, the number of candidates considered is much smaller: $O(K)$, where K is the number of motifs since only patterns that frequently occur in a class can be *representative*.

In addition to speeding up the algorithm, grammar induction, by design, grows the lengths of the initial patterns when constructing grammar rules, thus eliminating the need for searching an optimal pattern length exhaustively – a procedure that is common to most of sliding window-based shapelet techniques [36][10][27].

Since GI requires discrete input, our algorithm transforms real-valued time series into discrete values using Symbolic Aggregate approXimation (SAX) [18]. The algorithm operates in the approximate symbolic space inferring a grammar and generating a set of candidate patterns through the analysis of the grammar hierarchy in linear time. Next, the algorithm maps the discovered patterns back into real values and continues with pattern refinement using clustering. The cluster centroids (or medoids) are then reported as the best class-specific motifs, among which we select the most representative ones by verifying their classification power at the final step.

Figures 2 and 3 show examples of representative patterns discovered by our technique in two datasets: CBF, a synthetic dataset [22], and Coffee, a real dataset [2]. Representative patterns discovered in CBF highlight the most distinctive features in each of the three classes: a plateau followed by the sudden rise then followed by a plateau in Cylinder, the increasing ramp followed by a sudden drop in Bell, and a sudden rise by a decreasing ramp in Funnel. Representative patterns discovered in the Coffee dataset also correspond to the most distinctive natural features which not only include the discriminative caffeine and chlorogenic acid bands, but the spectra corresponding to other constituents such as carbohydrates, lipids, etc. [2].

Since we use a different selection criterion, the representative patterns discovered by our technique are different from the shapelets or patterns found by other subsequence-based techniques, thus providing a complementary functionality

that can be used for exploratory studies. For example, the representative patterns discovered in CBF and Coffee datasets by our approach are different from the shapelets discovered by Fast Shapelets [27], a well-known shapelet discovery algorithm which we use for experimental comparison. For the CBF dataset, Fast Shapelets reports two branching shapelets that correspond to sudden rises in Cylinder and Funnel classes. For the Coffee dataset, Fast Shapelets reports a single branching shapelet corresponding to the caffeine spectra band (Arabica).

Note that the discovery of class-specific motifs, which is an integral part of our algorithm, also offers a unique advantage that extends beyond the classification task. Differing from the traditional notion of time series motifs [17][3], which can either be repeated subsequences of a fixed length within a long time series, or repeated time series instances within a group of data (e.g. shape motifs [16]), our class-specific motifs are variable-length sub-patterns that occur frequently in many time series of a data group. They are, in a sense, related to time series subspace clusters [15]. Therefore, our approach provides an efficient mechanism to discover these subspace patterns without exhaustively searching through all subsequences. Throughout the paper, we will use the terms “class-specific subspace motifs” and “class-specific motifs” interchangeably.

Figure 2: The Cylinder-Bell-Funnel (CBF) dataset and the best representative patterns for its classes discovered with the proposed technique.

Figure 3: Two classes from the Coffee dataset and the best representative patterns.

As we shall demonstrate, in addition to the excellent exploratory characteristics, our approach achieves competitive classification accuracy compared to the state-of-the-art techniques: nearest neighbor classifiers, characteristic subsequence-based classifier (SAX-VSM), and shapelet-based classifiers, while maintaining great efficiency.

The rest of the paper is organized as follows: Section 2 discusses related work and background materials. We describe our approach for finding representative patterns in Section 3, and discuss parameter optimization in Section 4. Section 5 presents experimental results. We demonstrate the utilities of our approach with two case studies in Section 6, and conclude in Section 7.

2. RELATED WORK AND BACKGROUND

2.1 Notation and definition

To precisely state the problem at hand, and to relate our work to previous research, we will define the key terms used throughout this paper. We begin by defining our data type, time series:

Time series $T = t_1, \dots, t_m$ is a set of scalar observations ordered by time.

Since we focus on finding local patterns that are representative of a class, we consider time series subsequences:

Subsequence S of time series T is a contiguous sampling t_p, \dots, t_{p+n-1} of points of length $n \ll m$ where p is an arbitrary position, such that $1 \leq p \leq m - n + 1$.

Typically subsequences are extracted from a time series with the use of a sliding window:

Sliding window subsequence extraction: for a time series T of length m , and a user-defined subsequence length n , all possible subsequences of T can be found by sliding a window of size n across T .

Given two time series subsequences S_1 and S_2 , both of length n , the distance between them is a real number that accounts for how much these subsequences are different, and the function which outputs this number when given S_1 and S_2 is called the **distance function** and denoted $Dist(S_1, S_2)$. One of the most commonly used distance functions is the **Euclidean distance**, which is the square root of the sum of the squared differences between each pair of the corresponding data points in S_1 and S_2 .

Closest (i.e. best) match: Given a subsequence S and a time series T , the time series subsequence T_p of length $|S|$ starting at position p : $0 < p < |T| - |S|$ is the closest match of S if $Dist(S, T_p) \leq Dist(S, T_k)$, where T_k is a subsequence of T starting at any position k : $0 \leq k < |T| - |S|$, and $k \neq p$. The $Dist(S, T_p)$ is the **closest match distance**.

Time series pattern is a subsequence that possesses certain interesting characteristics. For example it can be a subsequence that occurs frequently, i.e. whose observance frequency is above some arbitrary threshold t . A frequently occurring subsequence is also called **time series motif**.

Class-specific motif: Given a class C and a set of training instances X_C , a class-specific motif M for C is a subsequence pattern S in C consisting of a set of similar subsequences from different training instances such that $count(S) \geq (\gamma \cdot |X_C|)$, where $0 < \gamma \leq 1$. This states that a pattern is considered frequent if it appears in at least γ of the training instances in the class. We will describe what we mean by “similar” in a later section.

Representative patterns: The most discriminative subsequences among the class motifs for class C are selected as the representative patterns for the class. The number of the representative patterns for each class is dynamically determined by the algorithm.

We will describe how to measure the “representativeness” and discriminative power of the candidate patterns in a later section.

Time Series Transformation: The set of the closest match distances between a time series T and the (candidate) representative patterns can be viewed as a transformation of $T \in \mathbb{R}^{n \cdot m}$ into $T' \in \mathbb{R}^{n \cdot K}$, where K is the total number of the representative patterns from all classes.

2.2 Related work

Classification of time series has attracted much interest from the data mining community in the past two decades

[4][36][5][13][21][28][25][33][20][35][34]. Nevertheless, to date, the simple nearest neighbor classification is the most popular choice due to its simplicity and effectiveness [32]. Therefore, a large body of work on time series classification has focused on the nearest neighbor classification improvement by developing new data representations or distance measures [32]. To date, a nearest neighbor classification with an effective distance measure like Dynamic Time Warping (DTW) outperforms many existing techniques [32].

Among the proposed alternatives, many methods focus on finding local patterns in time series as predictive features of the class [5]. Recently, Ye and Keogh introduced a novel concept called time series “shapelet”. A shapelet is an exact time series subsequence that is “maximally representative” of a class [36]. Once found, a shapelet-based technique classifies an unlabeled time series by computing its similarity to the shapelet. The original shapelet technique proposed by the authors constructs a decision tree-based classifier which uses the shapelet similarity as the splitting criterion. While effective and interpretable, the original shapelet discovery technique is computationally intensive.

Numerous improvements were proposed. The Logical Shapelets [20] extends the original work by improving the efficiency and introducing an augmented, more expressive shapelet representation based on conjunctions or disjunctions of shapelets. Fast Shapelets [27] improves the efficiency of the original shapelets algorithm by exploiting the projections into a symbolic representation. Learning Shapelets [7] proposes a new mathematical formalization that iteratively reduces the shapelet search space by computing a classification precision-based objective function.

The “Shapelet Transform” [10] technique finds the best K -shapelets and transforms the original time series into a vector of K features, each of which represents the distance between a time series and a shapelet. This technique can thus be used with virtually any classification algorithm.

SAX-VSM [31] is another approximate algorithm that enables the discovery of local class-characteristic (representative) patterns based on the similar pattern-discrimination principle via **tf*idf**-based patterns ranking [29]. While similar to our notion of representative patterns, the length of SAX-VSM-generated patterns equals to the sliding window length. In addition, the algorithm makes no additional effort to prune the discovered patterns, yielding a large sparse matrix of pattern weights.

Our algorithm can be related to the concept of mining interesting frequent patterns reviewed in [9], as it is essentially the selection of “interesting” pattern subset from a frequent pattern set. In our case, we regard the representative power of a pattern as its interestingness measure.

3. RPM: REPRESENTATIVE PATTERN MINING FOR CLASSIFICATION

The classification algorithm we propose consists of two stages: (a) Learning the representative patterns. (b) Classification using the representative patterns.

In the training stage, the algorithm identifies the most representative patterns for each class from the training data by 3 steps: (i) pre-processing training data; (ii) generating representative pattern candidates from processed data; (iii) selecting the most representative patterns from candidates.

Once the representative patterns are learned, we trans-

form the training data into a new feature space, where each representative pattern is a feature and each training time series is represented as a vector of distances to these patterns. We can then build a classifier from the transformed training data.

We will describe the algorithm in detail below, starting with the classification stage.

3.1 Time series classification using representative patterns

To classify a time series using the representative patterns learned from the training stage, the first step is to transform the test data $T \in \mathbb{R}^{n \cdot m}$ into a feature space representation $T' \in \mathbb{R}^{n \cdot K}$ by computing distances from T to each of the K representative patterns from all classes. The transformed time series is thus represented as a fixed-length vector – a universal data type which can be used with many of the traditional classification techniques. In this paper, we use SVM [24] for its popularity, but note that our algorithm can work with any classifier.

3.2 Training stage: Finding representative patterns

As mentioned previously, our goal is to find the most representative and distinctive patterns for each of the time series classes. These class-specific patterns should satisfy two requirements: (i) they should be class-specific motifs, i.e. shared by at least γ (a fraction) of the time series in the class; and (ii) they should enable the discrimination between the current and other classes – the capacity measured with a scoring function discussed below.

At the high level, the algorithm can be viewed as a succession of three steps. First, the algorithm performs data pre-processing for each class in the training data, by concatenating all instances from the same class into a long time series, and discretizing the concatenated time series. Second, the algorithm finds frequent patterns via grammar inference and forms the candidate pool for each class. Third, it refines the candidates pool by eliminating redundant and non-discriminating patterns, and outputs patterns that represent the class the best, i.e., the representative patterns.

In our previous work, we proposed GrammarViz (v2.0), which uses time series discretization and grammar inference for time series motif discovery and exploration [17][30]. We observe that the same approach can be leveraged to find class-specific subspace motifs, thus enabling the classification as well.

3.2.1 Step 1: Pre-processing

We prepare the training data for subspace pattern discovery by concatenating all training time series from the same class into a single long time series. We note that the concatenation step is not required for our learning algorithm and can in fact be skipped. The reason for concatenating the training instances is for visualization purpose only, as will be shown in Figure 4.

Next, we discretize the concatenated time series into a sequence of tokens for grammar induction using Symbolic Aggregate approXimation (SAX) [18]. More specifically, we apply SAX to *subsequences* extracted from the concatenated time series of a training class via a sliding window. SAX performs subsequence discretization by first reducing the dimensionality of the subsequence with Piecewise Aggregate

Approximation (PAA) [12]. Towards that end, it divides z -normalized subsequence into w equal-sized segments and computes a mean value for each segment. It then maps these values to symbols according to a pre-defined set of breakpoints dividing the distribution space into α equiprobable regions, where α is the alphabet size specified by the user. This *subsequence discretization* process outputs an ordered list of SAX words, where each word corresponds to the leftmost point of the sliding window. Two parameters affect the SAX transform granularity – the number of PAA segments (PAA size) and the SAX alphabet size.

Since neighboring subsequences extracted via a sliding window share all points except one, they are similar to each other and often have identical SAX representations. To prevent over-counting a pattern, we apply numerosity reduction [17]: if in the course of discretization, the same SAX word occurs more than once consecutively, instead of placing every instance into the resulting string, we record only its first occurrence.

As an example, consider the sequence $S0$ where each word (e.g. aba) represents a subsequence extracted from the concatenated time series via a sliding window and then discretized with SAX. The subscript following each word denotes the starting position of the corresponding subsequence in the time series.

$S0 = aba_1 bac_2 bac_3 bac_4 cab_5 acc_6 bac_7 bac_8 cab_9 \dots$

With numerosity reduction, $S0$ becomes:

$S1 = aba_1 bac_2 cab_5 acc_6 bac_7 cab_9 \dots$

Numerosity reduction not only reduces the length of the input for the next step of the algorithm (hence making it more efficient and reducing its space requirements) and simplifies the identification of non-overlapping time series motifs by removing “noise” from overlapping subsequences. Most importantly, numerosity reduction enables the discovery of representative patterns of varying lengths as we show next.

3.2.2 Step 2: Generating representative pattern candidates

In this step, we use grammar induction to identify repeated patterns in the concatenated time series, and generate a *representative pattern candidates pool* from these patterns. The algorithm is outlined in Algorithm 1. The sequence of SAX words obtained from the pre-processing step is fed into a context-free grammar induction algorithm (Algorithm 1, Line 7). We use Sequitur, a string compression algorithm that infers a context-free grammar in linear time and space [23]. We choose Sequitur due to its efficiency and reasonably good compression capability, but note that our technique also works with other (context-free) GI algorithms. When applied to a sequence of SAX words, Sequitur treats each word as a token and recursively reduces all *diagrams*, i.e. consecutive pairs of tokens (terminals or non-terminals), occurring more than once in the input string to a single new non-terminal symbol representing a grammar rule.

Consider the grammar induced by Sequitur from the input string $S1$:

Grammar Rule	Expanded Grammar Rule
$R0 \rightarrow aba R1 acc R1$	$aba_1 bac_2 cab_5 acc_6 bac_7 cab_9$
$R1 \rightarrow bac cab$	$bac cab$

In this grammar, $R1$ describes a simplified version of the

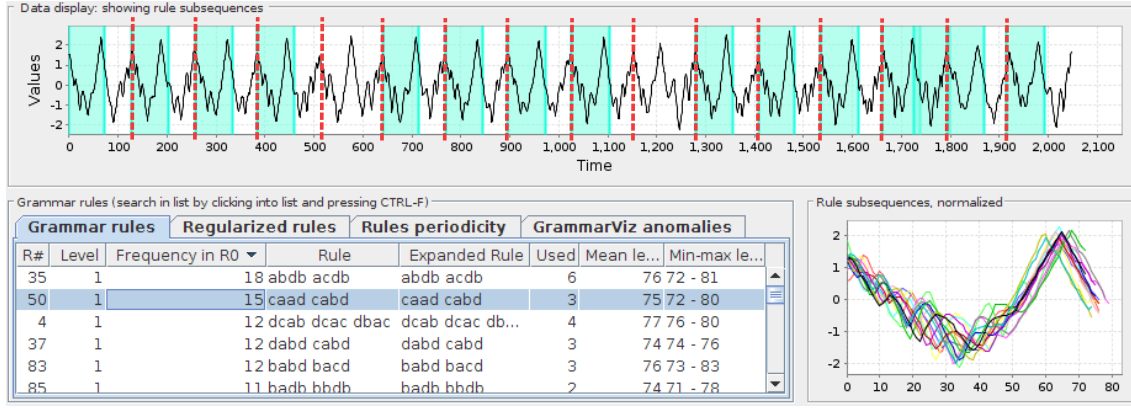

Figure 4: RPM pre-processing visualization with GrammarViz 2.0 [30]. The time series from Class 4 of SwedishLeaf dataset were concatenated, discretized, Sequitur grammar was inferred, and one of the frequent motifs selected. Note that the grammar rule-corresponding subsequences vary in length from 72 to 80. The length of the original time series before concatenation is 128 as indicated by dotted lines. Note that one of time series does not contain the pattern and another contains it twice.

repeated pattern $[bac\ cab]$, which concurrently maps to two substrings of different lengths from S_0 : $[bac_2\ bac_3\ bac_4\ cab_5]$ (length of 4) and $[bac_7\ bac_8\ cab_9]$ (length of 3), respectively.

By keeping SAX words' offsets throughout the procedures of discretization and grammar induction, we are able to map rules and SAX words back to their original time series subsequences. Since each SAX word corresponds to a *single point* of the input time series (a subsequence starting point), $R1$ maps to subsequences of variable lengths ([2-5] and [7-9]). Figure 4 shows an example of the recurrent subsequences found in the concatenated time series from Class 4 of the Swedish Leaf dataset. Note, that when processing a concatenated time series, the algorithm does not consider the subsequences that span time series junction points in order to avoid concatenation process artifacts.

Algorithm 1 Finding repeated patterns

```

1: function FINDCANDIDATES( $Train, SAXParams, \gamma$ )
2:    $candidates \leftarrow \emptyset$ 
3:    $allCandidates \leftarrow \emptyset$ 
4:   for each  $TrainClassI$  in  $Train$  do
5:      $cTS \leftarrow CONCATENATE(TS(TrainClassI))$ 
6:     // {build grammar avoiding junctions (see Fig. 4)}
7:      $allRepeats \leftarrow MODIFIEDGI(cTS, SAXParams)$ 
8:      $refinedRepeats \leftarrow \emptyset$ 
9:     // {r is repeated subsequences from a row in Fig. 4}
10:    for each  $r$  in  $allRepeats$  do
11:       $clusters \leftarrow CLUSTERING(r)$ 
12:       $refinedRepeats.addAll(clusters)$ 
13:    for each  $cluster$  in  $refinedRepeats$  do
14:      if  $cluster.size > \gamma \cdot |I|$  then
15:         $centroid \leftarrow GETCENTROID(cluster)$ 
16:        // {candidates for class I}
17:         $candidates.add(centroid)$ 
18:        // {candidates for all classes}
19:       $allCandidates.add(candidates)$ 
20:  return ( $allCandidates$ )

```

Refining repeated subsequences: Every grammar rule induced from Sequitur describes an *approximate* repeated pattern (our candidate motif) observed in time series; however, corresponding exact subsequences may differ significantly depending on the SAX granularity. To select the most representative of the frequent symbolic patterns (and essen-

tially of the training class), we use hierarchical clustering algorithm (complete-linkage) to cluster all rule-corresponding subsequences based on their similarity (Algorithm 1, Line 11). Note that the purpose of applying clustering here is to handle the situation where a candidate motif found by grammar induction algorithm may contain more than one group of similar subsequences. In this case, we should partition the subsequences into sets of clusters, each of which corresponds to one motif. To determine the appropriate number of clusters, we first set the number of clusters as *two*. If the cluster sizes are drastically different, e.g. one of the clusters contains less than 30% of subsequences from the original group, we do not split the original group. If both clusters contain sufficient numbers of subsequences, we will continue to split them into smaller groups. The partitioning stops when no group can be further split (Algorithm 1, Line 12).

Consistent with Section 3.2 requirement (i), if the size of a cluster is smaller than the specified threshold γ , the cluster is discarded. If a cluster satisfies the minimum size requirement, its centroid is added to the representative patterns candidates pool for a class (Algorithm 1, Line 14-15). Note an alternative is to use the medoid instead of centroid. As outlined in Algorithm 1, this refinement procedure outputs a list of representative pattern *candidates* for all classes.

3.2.3 Step 3: Selecting the most representative patterns

The candidate patterns obtained so far are the frequent patterns that occur in a class. However, some of them may not be class-discriminative if they also occur in other classes. Addressing this issue, we prune the candidate patterns pool with Algorithm 2 whose input is the pool of candidate patterns identified from the previous step, and the entire training dataset. The algorithm outputs the set of class-specific patterns.

Remove Similar Patterns: The representative pattern candidates are repeated patterns found by the grammar induction algorithm applied to the discretized time series. Due to the aggregation, some structurally similar subsequences may be mapped to slightly different SAX strings, e.g. differ by one letter. Feeding such patterns to the subsequent step (selecting representative patterns) will slow down the search

Algorithm 2 Find distinctive patterns

```

1: function FINDDISTINCT(Train, allCandidates)
2:   candidates  $\leftarrow \emptyset$ 
3:    $\tau \leftarrow \text{COMPUTETHRESHOLD}$ 
4:   // {Remove similarities in allCandidates}
5:   for each c in allCandidates do
6:     isNonSimilar  $\leftarrow \text{true}$ 
7:     for each cns in candidates do
8:       // {c and cns may have different length}
9:       dist  $\leftarrow \text{COMPUTECLOSESTMATCHDIST}(c, c_{ns})$ 
10:      if dist <  $\tau$  then
11:        if cns.frequent < c.frequent then
12:          // {The frequency in concatenated TS}
13:          candidates.remove(cns)
14:          candidates.add(c)
15:          isNonSimilar  $\leftarrow \text{false}$ 
16:          break();
17:      if isNonSimilar then
18:        candidates.add(c)
19:    // {Transform TS into new feature space where each fea-
    // ture is the distance between time series and a candidate}
20:    TransformedTrain  $\leftarrow \text{TRANSFORM}(\text{Train}, \text{candidates})$ 
21:    // {Perform feature selection algorithm on new data}
22:    selectedIndices  $\leftarrow \text{FSALG}(\text{TransformedTrain})$ 
23:    // {Select patterns according to indices}
24:    patterns  $\leftarrow \text{SELECT}(\text{candidates}, \text{selectedIndices})$ 
25:    return (patterns)

```

when removing correlated patterns in feature selection step.

In order to resolve this issue, our algorithm removes similar candidates from the candidate set, as shown in Algorithm 2, Lines 5 – 18. Before the removal, it computes a threshold used to determine if two patterns are similar. The threshold (Alg. 2, Line 3) is determined as follows: (i) Compute pairwise distances of subsequences within each refined grammar rule (i.e. the final clusters from Algorithm 1). (ii) Sort the distances in ascending order. (iii) Take the distance at the 30-th percentile as the threshold τ for similarity. We will show the effect on accuracy and running time with different values of τ in the experimental section.

Select Representative Patterns: After refining the representative pattern candidates pool from the previous steps, we transform the original time series into a distance feature vector by computing the closest match distance between each time series and all the candidate patterns. As an example, two patterns in dataset ECGFiveDays are shown in Figure 5, and the transformed training data is shown in Figure 6. The original time series from the two classes look visually similar. However, once we transform the raw time series into the two-dimensional feature vector (one feature from each class in this case), it is easy to separate the two classes. As can be seen in Figure 6, the transformed data is linearly separable.

Since the transformation uses all the candidates as new features, a feature selection step is needed to select the most distinctive features. Each feature represents the distance from the original time series to one of the candidate patterns. Thus, the features selected represent the most representative patterns. Any feature selection algorithms can be applied here. In this work, we use the correlation-based feature selection from [8], since it is capable of identifying features that are highly correlated with the class. After feature selection, the selected patterns will be used to classify future time series. Note that the number of selected patterns for each class is dynamically determined by the feature se-

Figure 5: Two classes from the ECGFiveDays dataset and the best representative patterns.

lection algorithm.

4. PARAMETER SELECTION AND CLASSIFICATION WITH DIFFERENT SAX PARAMETERS

As shown in Algorithm 1, there is a parameter vector *SAXParams* in the input. The vector consists of three SAX discretization parameters, namely the sliding window size, PAA size, and the SAX alphabet size. In this section, we shall describe our algorithm for the optimal SAX parameters selection. Since time series data in different classes may have varying characteristics, a parameter set that is optimal for one class may not be optimal for another. Therefore, the parameter optimization is performed for each class.

4.1 Search for the best SAX parameters exhaustively

One way to find the optimal parameter set is by brute force grid search – as shown in Algorithm 3. The algorithm tests all parameter combinations within a specified range and selects the optimal set (the one that results in the best F1 measure score from five-fold cross validation on the validation data set). For each parameter combination candidate, the grid search algorithm first divides the original training data into training and validation data 5 times for 5 different splits. For each split, the algorithm invokes Algorithms 1 and 2 to obtain the representative patterns

(Lines 8-9). The validation is performed on the validation data set (Line 12) with a five-fold cross validation. The F1 measure is computed using the classification result for each class. The parameter combination with the best F1 measure for each class is selected as the optimal parameters for the class.

Algorithm 3 SAX Parameter selection (Brute-Force)

```

1: function PARAMSELECT(ParamsRange, OriginalTrain)
2:   for each Class I do
3:     bestSoFarForI  $\leftarrow$  0
4:   for each SAXPs in ParamsRange do
5:     // {Repeat 5 times for different splits}
6:     while iteration < 5 do
7:       {train, validate}  $\leftarrow$  SPLIT(OriginalTrain)
8:       candidates  $\leftarrow$  FINDCANDIDATES(train, SAXPs,  $\gamma$ )
9:       patterns  $\leftarrow$  FINDDISTINCT(train, candidates)
10:      validatet  $\leftarrow$  TRANSFORM(validate, patterns)
11:      // {fMeasure is the f1 measure of each class}
12:      fMeasure  $\leftarrow$  5FOLDS CV(validatet)
13:      for each Class I do
14:        if fMeasure.i > bestSoFarForI then
15:          bestParamForClassI  $\leftarrow$  SAXPs
16:          bestSoFarForI  $\leftarrow$  fMeasure.i
17:      iteration ++
18:    for each Class I do
19:      bestParams.add(bestParamForClassI)
20:  return (bestParams)

```

Instead of running Algorithm 3 completely to find the best parameter set, pruning can be performed by the observed number of repeated patterns. In Line 8 of Algorithm 3, if no candidate for a class is returned because all repeated patterns for that class have frequency below the specified threshold (γ), the algorithm abandons the current iteration and proceeds with the next parameter combination. The intuition rests upon the fact that given the number of time series in the training data, we can estimate the required minimal frequency for the repeated patterns.

4.2 Searching for the best SAX parameters using DIRECT

We optimize the search for the best discretization parameters set by using the Dividing RECTangles (DIRECT) algorithm [11] which is a derivative-free optimization scheme that possesses local and global optimization properties, converges quickly, and yields a deterministic optimal solution. DIRECT is designed to deal with optimization problems of the form:

$$\min_x f(x), f \in \mathbf{R}, x, X_L, X_U \in \mathbf{R}, \text{ where } X_L \leq x \leq X_U$$

where $f(x)$ is the objective (error) function, and x is a parameters vector. The algorithm begins by scaling the search domain to a unit hypercube. Next, it iteratively performs a sampling procedure consisting of two steps: (i) partitioning the hypercube into smaller hyper-rectangles and (ii) identifying a set of potentially-optimal hyper-rectangles by sampling their centers. Iterations continue until the error function converges. DIRECT is guaranteed to converge to the global optimal function value as the number of iterations approaches infinity and the function is continuous in the neighborhood of a global optimum [11]. If interrupted at any iteration, for example after exhausting a time limit, the algorithm reports the best-so-far parameters set.

Since SAX parameters are integer values, we round the values reported by DIRECT to the closest integers when optimizing their selection for our cross validation-based error function (one minus $fMeasure$, as described in Section 4.1). While rounding affects the DIRECT convergence speed, this approach is not only much more efficient than the exhaustive search, but is also able to perform a time-constrained parameter optimization by limiting the number of iterations.

4.3 Classification with class-specific trained parameters

With the best SAX parameters learned from Section 4.2, the representative patterns can be obtained by calling Algorithms 1 and 2. To classify future instances, we follow the classification procedure described in Section 3.1. However, with the class-specific parameter optimization, we need to add more steps to the classification procedure to account for the adaptive parameter sets for different classes. Different classes may have different best SAX parameter combinations (SPCs). We learn the best SPCs for each class respectively as described previously. Then we apply Algorithms 1 and 2 to obtain the representative patterns for each SPC. We combine all these representative patterns together and remove the correlated patterns by applying feature selection again. We then obtain the final set of representative patterns, which will be used as the input for the algorithm described in Section 3.1 to classify test data.

5. EXPERIMENTAL EVALUATION

5.1 Setup and Baseline

We evaluate the classification performance of our technique on the standard time series archive from the UCR repository [14]. Information on the datasets is shown in Table 1. The code and datasets used for the case study (discussed next section) are available on [1]. We compare our method Representative Pattern Mining (RPM) with five other classification techniques, among which are two nearest-neighbor classifiers based on the global distance measures: Euclidean distance (1NN-ED) and DTW with the best warping window (1NN-DTWB), and three classifiers based on the use of class-characteristic local patterns: Fast Shapelets (FS) [27], SAX-VSM [31] and Learning Shapelets (LS) [7]. These three subsequence-based techniques rely on different numbers of patterns for classification – while Fast Shapelets uses a minimal number of patterns to build a classification tree, SAX-VSM accounts for all patterns extracted via sliding window in each of the class-representing weight vectors. Learning Shapelets has the best accuracy so far.

5.2 Classification Accuracy

Table 1 shows the classification error rates for all six methods on the UCR datasets. The best error rate for each dataset is denoted with boldface. In addition, Figure 7 shows the summary comparison of our proposed technique with other methods. The results shown are with parameter optimization, and the γ (minimum cluster size) is set to be 20% of the training size for the class. From the results, our method is the second best on classification accuracy among these six methods. We slightly lose to the Learning Shapelets method, which has the most “wins” in classification. However, the p-value of wilcoxon test is 0.834 > 0.05, so the difference is not significant with a confidence

Table 1: Datasets description and the classification error rates.

of 95%. Moreover, as we can visually inspect from Figure 7, the error rate difference between Learning Shapelets and RPM is very small — most of the points are located around the diagonal. In the next section, we will show that our method is much faster than the Learning Shapelets method.

5.3 Efficiency

The pre-processing, discretization and Sequitur grammar induction all have linear time complexity in the size of training data and, in practice, can be done simultaneously, since they process data sequentially. To select the best representative patterns for each class, we need to first cluster the candidate motifs identified by the grammar rules. The time required for clustering depends on the number of motif instances identified. Suppose there are (on average) u motif instances in each grammar rule, then the complexity is $O(u^3 \cdot |rules|)$ for hierarchical clustering. The centroids of the qualifying clusters are the pattern candidates. For each pattern candidate, we perform subsequence matching to identify the best matches ($O(|Candidates| \cdot |Train|)$). Even though the number of pattern candidates for each class is relatively small compared to the training size, this step seems to be the bottleneck of the training stage due to the repeated distance call. We use early abandoning strategy [32] to speed up the subsequence matching, but other options are possible such as approximate matching. The training needs to be repeated for each class. Thus, the training complexity is $O(|Train| + c \cdot (u^3 \cdot |rules| + |Candidates| \cdot |Train|))$, where c is the number of classes, and u is the average number of motif instances in each grammar rule.

If the best SAX parameters are known, our algorithm is fast — in this case, simply using the classification method described in Section 3.1 completes the classification task. To get the best SAX parameters, we evaluated cross-validation based parameter selection techniques, exhaustive search and DIRECT described in section 4.1 and 4.2. Exhaustive search was found time-consuming even with early abandoning, therefore we use DIRECT. The overall running time using DIRECT in the worst case is $O((|Train| + c \cdot (u^3 \cdot |rules| + |Candidates| \cdot |Train|)) \cdot R)$, where R is the number of SAX parameters combinations tested by DIRECT algorithm. From the experiments on 42 UCR time series datasets, the average value for R is less than 200, which is smaller than the average time series length 363. In most of the R evaluations, the program terminated search early because of the minimum motif frequency requirement (Sec. 3.2). The classification time, compared to training, is negligible.

We compare the total running time of our algorithm using DIRECT with that of Fast Shapelets (FS) and Learning Shapelets (LS), and the results are shown in Table 2. Even when accounting for parameter selection, our algorithm is comparable to Fast Shapelets in running time, and as shown in Table 1, our method is significantly more accurate than Fast Shapelets (p-value equals 0.002). Compared to Learning Shapelets, our method is a lot faster. The greatest speedup we achieve through these 42 datasets is 1587X on dataset Adiac, and the average speedup is 178X. The experiment results show that our method is comparable to the fastest algorithm in speed and to the most accurate algorithm in accuracy.

In Section 3.2.3, we use τ as the threshold to remove similar patterns. We choose the value at the 30th percentile of the pair-wise distances as the threshold. We also compare

the results using the 10th, 50th, 70th, and 90th percentiles. The running time and classification error changes are shown in Figure 9. The average running time and classification error changes on the 42 UCR data set are shown in Table 3. The average standard deviation for running time is 268.71 seconds, and 0.014 for classification error.

higher value for this parameter to achieve a fast speed and still could maintain a high accuracy.

The τ value used for the experiment results (classification error and running time) shown in Tables 1 and 2 is set as 30% because it gives the best accuracy and still has a fast running speed.

6. CASE STUDY

In this section we demonstrate the application of our method to classification of rotated time series data and Medical Alarm data. We compare results with 1NN Euclidean distance, 1NN DTW with the best warping window, SAX-VSM, Fast Shapelets, and Learning Shapelets classifiers.

6.1 Rotation invariance

Many global-distance-based techniques do not work well if the time series data are shifted or out of phase. One type of distortion is shape-converted time series [19], e.g. by radial scanning of the shape profile to convert the image into a “time series.” Several datasets in the UCR repository are shape-converted time series, e.g. OSU Leaf, Swedish Leaf, Shields, etc. In this section we demonstrate the rotation- or shift-invariance of our technique on a number of shifted datasets. To shift or “rotate” a time series, we randomly choose a cut point in the time series, and swap the sections before and after the cut point. This transformation is equivalent to starting the radial scanning of the shape at a different position on the shape profile. The out-of-phase phenomenon is also common in many other real-world time series data such as video. Figure 10 illustrates the original GunPoint dataset time series and their rotation.

In our experiments, we leave the training set unmodified, and shift only the test data. The rationale is that while it is not uncommon for one to pre-process and create a “cleaned” version of training data to build a good model, it is less reasonable to expect that the test data will be in the same cleaned format. In other words, we learn the patterns on existing training data, but modify the test data to create rotation distortion, in order to evaluate the robustness of our technique.

It is possible that the rotation cuts the best matching subsequence of the test time series. To handle this, we introduce

Table 4: Classification error rate on shifted time series

Dataset	1NN-ED	1NN-DTWB	SAX-VSM	LS	RPM
Coffee	0.536	0.460	0.000	0.036	0.000

# best (including ties)	0	0	3	0	4

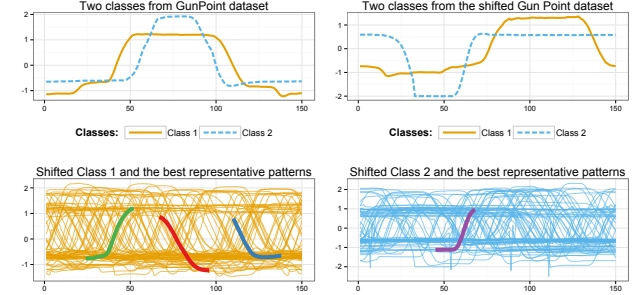

Figure 10: Shifted GunPoint dataset and the best representative patterns.

a new strategy to the test time series transformation step to make our algorithm rotation invariant. When transforming a raw time series into the new feature space of the closest match distances, our algorithm needs to calculate the distance between the time series to each representative pattern. In order to solve the aforementioned problem, our algorithm will build another time series. For example, when transforming a rotated time series A , we generate another new time series B by cutting A from its midpoint and swapping the first and the second halves. By doing so, B will contain the concatenation of A ’s tail and head. If the best-matching subsequence happens to be broken up due to the rotation (A), then by rotating it again at the midpoint, one of A or B will contain the entirety of the best-matching subsequence. When computing the distance of A to a pattern p , besides calculating a distance d_a between A and p , the algorithm will also calculating another best match distance d_b between B and p . The minimal distance of these two will be used as the distance from A to p . This solution overcomes the potential problem that arises when the best matching pattern is cut into different parts due to the rotation.

The classification error rates of the rotated data are shown in Table 4. The accuracy of our method or SAX-VSM does not change very much from the unrotated version (though our technique seems to be more robust, with 4 wins), while the error rates of 1NN Euclidean distance and 1NN DTWB increase drastically.

6.2 Medical Alarm

In this case study, we use the medical alarm data from Intensive Care Unit (ICU) database (MIMIC II database from PhysioNet) [6]. We used arterial blood pressure (ABP) waveforms to create the dataset used in this work.

6.2.1 Normal or Alarm

We selected two types of ABP series segments: those that triggered an alarm and those that did not. The data used are all from the same patient. The selected dataset contains 52 time series of length of 2126. Each of the time series represents a segment of arterial blood pressure (ABP) waveform

in a 17 second time range. The *Normal* class consists of segments without any alarms, whereas the *Alarm* class consists of segments that triggered the bedside patient monitors and were verified by the domain expert as true alarms. The dataset contains 26 time series in class *Normal* and 26 in class *Alarm*. Training and test data are split into sets of 16 and 36 time series respectively. Examples of medical alarm data from each class are shown in Figure 11.

The first row of Table 5 shows the accuracy of competing classification techniques. Figure 11 shows the representative patterns from medical alarm time series and their best matches on test data. Our method (RPM) achieves the best accuracy on this dataset.

Table 5: Classification error rate on Medical Alarm data

Dataset	1NN- ED	1NN- DTWB	SAX- VSM	FS	LS	RPM
NormalOrAlarm	0.333	0.333	0.167	0.306	0.111	0.056
FiveAlarmTypes	0.760	0.360	0.350	0.485	0.260	0.300

Figure 11: Normal or Alarm data and the best representative patterns.

6.2.2 Five types of alarm

In PhysioNet’s MIMIC II database, there are five categories of critical arrhythmia alarms produced by a commercial ICU monitoring system: *Asystole*, *Extreme Bradycardia*, *Extreme Tachycardia*, *Ventricular Tachycardia*, and *Ventricular Fibrillation/Tachycardia*. We collected a dataset by taking the segments of an arterial blood pressure waveform. Each segment contains a verified alarm. The objective is to classify the alarm time series into one of the five types of alarms.

The training set has 50 examples, 10 for each class. The test set has 100 examples, 20 for each class. All time series have the same length of 2126 (17 seconds). The time series example of each class, the representative patterns, and the best matches are shown in Figure 12. Table 5 shows the accuracy of competing classification techniques for this dataset.

Our method (RPM) has the second best accuracy on this dataset. We lose slightly to Learning Shapelets since we have 30 incorrectly classified instances compare to 26 with LS. However, our method finished in 1373 seconds compare to 86195 seconds of LS. The speedup of our algorithm over LS is 63X on this dataset.

7. CONCLUSIONS

In this work, we propose a novel method to discover representative patterns of time series, specifically for the problem of classification. We demonstrate through extensive

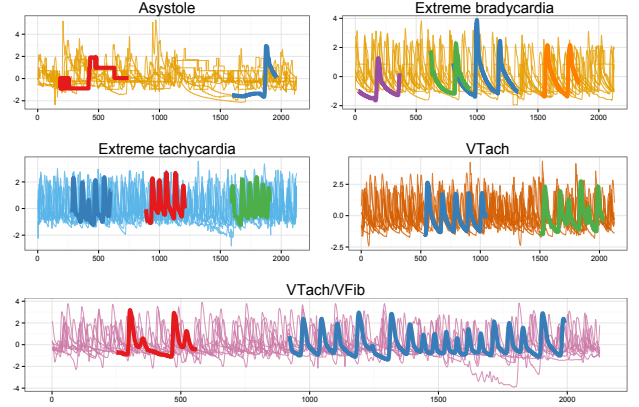

Figure 12: Five type of Medical Alarm and the best representative patterns.

experimental evaluation that our technique achieves competitive classification accuracy on the standard UCR time series repository, and is able to discover meaningful subspace patterns. The accuracy of our technique remains stable even when the data are shifted, while NN classifiers with global distance measures suffer from shift distortion. We also demonstrate that our technique outperforms existing techniques on a real-world medical alarm data that is extremely noisy.

In terms of efficiency, while our approach is competitive or better than other techniques, there are other optimization strategies that we can consider to speed up the algorithm even further. From profiling, we identified the bottleneck of the algorithm, which can be improved by adapting the state-of-the-art subsequence matching strategies [26]. Also, we used Euclidean distance as the base distance function for pattern matching. We will consider a more robust distance measure such as DTW in future work.

ABSTRACT

Traditional temporal association mining systems, once supplied with a specific parameter setting such as time periods of interest, minimum support and confidence, generate the rule set from scratch. This one-at-a-time paradigm forces the analysts to perform successive trial-and-error iterations to finally discover interesting temporal patterns. This process is not only prohibitively time and resource consuming, but also ineffective in providing meaningful feedback for improving the desired rule outcome.

In this work, we introduce the first solution to interactively explore temporal associations from evolving data at multiple levels of abstraction, henceforth referred to as *temporal association rule analytics (TARA)*. The offline rule preparation phase of the **TARA** infrastructure extracts the temporal associations from the raw data and compresses them into a knowledge-rich yet compact evolving parameter space (*EPS*) structure. The online exploration phase of **TARA** leverages this *EPS* structure to offer rich classes of novel exploration operations from parameter recommendations and time-travel queries to the discovery of hidden insights of associations with near instantaneous responsiveness. As demonstrated by our extensive experiments on real-world data sets, **TARA** accomplishes three to five orders of magnitude improvement over state-of-the-art approaches while offering a rich interactive exploration experience.

1. INTRODUCTION

1.1 Motivation

Nowadays batches of data are continuously transmitted from a rich variety of sources including websites, mobile devices and other data sources, henceforth referred to as *evolving datasets*. Discovering associations and their dynamics

hidden in such large evolving datasets has been recognized as critical for domains ranging from market products analysis, stock trend monitoring, targeted advertising to weather forecasting.

For example, in the retail businesses, the arrival of new fashions or gadgets may boost unprecedented sales while seasonal products may gain or lose customers' interest. Some products are purchased together more frequently in the days leading to a large sports event or during a traditional holiday like Thanksgiving. Companies such as Amazon, eBay, Walmart and other retail businesses apply temporal association mining techniques to their transaction logs to identify popular product combination at specific times and their behavior over time. Such information is critical for deciding the times when products can be placed together on a web page or configured into attractive bundle-offers to be used for recommendations to encourage sales.

Interactive data mining models, crucial for discovering knowledge from data, enable analysts to actively engage in the analysis process. State-of-the-art temporal association mining systems [2, 9, 14, 18], once supplied with a specific parameter setting, tend to generate the ruleset for each request from scratch. This one-at-the-time request model suffers from severe limitations described below.

1.2 Limitations of State-of-the-Art

Lack of instantaneous responsiveness. Lag in responsiveness is known to risk losing an analyst's attention during the exploration process. In applications like targeted ad placement such delay in decision making may prove to be the cause of missed business opportunities and thus a potentially huge loss in profit. Unfortunately, *temporal association mining algorithms* [2, 14] are known to be computationally intensive. To overcome this challenge, [18] pre-generates the *intermediate itemsets* that are subsequently used to derive the temporal associations instead of extracting them from the huge raw data store. With this promising one-time preprocessing strategy, the response time has been shown to be greatly reduced. However, the process of the final rule derivation remains a query-time task. This results in the shortcoming that the response times for mining such requests are not sufficient to support truly interactive exploration as confirmed by our experiments (Sec. 8).

Lack of parameter recommendations. Temporal association mining algorithms are parametrized not only by traditional measures like *support* and *confidence* but also by *time-variant* measures [11, 16, 17]. Parameter settings

*This work was partly supported by the National Science Foundation under grants IIS-1117139, CRI-1305258, IIS-0812027 and CCF-0811510 and Fulbright program.

used for one batch of data may produce insignificant rules for a newly incoming data batch. Thus the data analysts often must perform numerous successive trial-and-error iterations to find an appropriate parameter configuration out of a seemingly infinite number of possible settings. Existing state-of-the-art models tend to correspond to a black-box [2, 6, 9, 14, 18] - providing little to no feedback about which parameter settings best capture the analyst’s interest. To tackle this, [10] incorporates an indexing technique to swiftly produce parameter recommendations. However it is restricted to static data and thus does not support *time variant operations* essential for temporal association mining.

Lack of evolving ruleset comparison. Analysis of the data in finer time granularity may reveal that associations exist only in certain time periods. Some may fluctuate as new data arrives while others may remain stable. Furthermore, two seemingly similar parameter settings can generate different results. Systems like [2, 6, 14, 18] independently generate the ruleset for each parameter settings. Worse yet, analysts then have to go through a tedious process to manually investigate the results generated by different parameter settings to extract their differences. This can be extremely tedious and impractical for large data sets.

Lack of insights into the evolving associations. Given a parameter configuration, a system often generates a huge number of rules. Analysts would benefit from being able to quickly identify the most interesting ones, such as the most stable rules [11] within the last week, the most significant rules that occur every weekend, or the rules concerning specific products. Offering such rich insights into time-variant rule behavior would provide the analysts with the opportunity to leverage their domain knowledge to drive the discovery process. Unfortunately, most existing parameter-driven exploration systems [10, 16, 18] do not support the analyst in the discovery of such useful *time-sensitive* insights.

1.3 Research Challenges

To develop an interactive temporal analytic system, the following research challenges must be tackled.

Processing time-variant evolving data. Given a time-variant data set containing n unique items, the maximum number of possible associations are bounded by $3^n - 2^n + 1$ [10]. The significance of associations may vary over time, as newly incoming data may bring new items and associations. Being able to quickly extract these associations and their behavior w.r.t different time horizons to answer analysts’ requests is the key to providing an interactive mining experience. However, it is almost impossible to pre-generate all such information. Thus the system must have an efficient preprocessing strategy that pregenerates a minimal yet sufficient amount of information as its critical knowledge store to support interactive temporal association exploration.

Managing temporal associations for all parameters. Typical input parameters, such as *minimum support* and *confidence*, can be configured using any real number restricted to a certain range. Similarly, the time specification can be composed of one or multiple time periods along the continuous timeline. Clearly, an infinite number of possible parameter settings exists. Maintaining the corresponding ruleset for each parameter setting individually thus is impractical. Therefore, an efficient mechanism is needed to map the pregenerated temporal associations to the space of parameter settings.

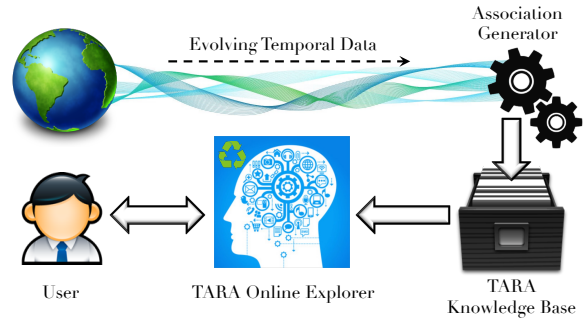

Figure 1: The TARA Approach

Maintaining parameter values for different time periods. The prominence level of an association may vary significantly for some associations while remaining stable for others. Such time-variant properties of parameter values may reveal important evolving patterns of an association in the evolving dataset. Yet keeping each single historical parameter value for each association is inefficient, resulting in large storage and search space. Therefore, a compact archive structure is needed to efficiently maintain the parameter values of the associations across time while supporting fast system access to retrieve any desired information.

Supporting advanced temporal association exploration. Rule mining algorithms tend to generate too many rules - making it extremely hard for the analysts to quickly identify the interesting ones. The problem of interestingness of temporal rules has been previously investigated [12, 17]. An interactive temporal association exploration system must integrate such interestingness measures to provide critical insights about the associations such as their evolving behaviors across time. The retrieved rules w.r.t particular parameter settings must be efficiently evaluated using these measures so that the instant responsiveness of the system is safeguarded.

1.4 The TARA Approach

We propose a novel temporal association rule analytics (TARA) framework that addresses the above challenges. The **TARA** infrastructure depicted in Fig. 1 employs an off-line preprocessing phase composed of Association Generator and Knowledge Base Constructor followed by TARA Online Explorer that enables analysts to interactively explore the evolving data with support by the knowledge base.

The Association Generator extracts temporal associations from the evolving data and compactly stores them in the Temporal Association Rule Archive (*TAR Archive*) of TARA knowledge base. Later, by request, the parameter values of a particular association w.r.t various fine granularities can be quickly computed without processing the raw data again. These pregenerated temporal associations are compressed into a knowledge-rich yet compact *evolving parameter space (EPS)* that encodes the relationships among the temporal associations. Next, the TARA knowledge base explicitly extracts and then models the distribution of the pregenerated temporal associations with respect to their parameters, e.g. support, confidence and time periods.

Beyond achieving speedup in response time, the online processing strategies leverage the *EPS* index to offer analysts an innovative “rule-centric panorama” into the temporal associations present within the evolving dataset. The framework supports rich classes of novel exploration opera-

tions from time-travel queries and parameter recommendations to evolving ruleset comparisons.

1.5 Contributions

Key contributions of this work include:

- We propose the first *interactive temporal association rule mining* analytics framework called **TARA** that enables analysts to explore associations across time and pinpoint appropriate parameter settings in a systematic way.
- The **TARA** model organizes the temporal associations in the space of query parameters. It abstracts the temporal associations at the coarse granularity of *time-aware stable regions* across multiple time periods.
- The **TARA** model is supported by *evolving parameter space (EPS)* index structure that indexes *time-aware stable regions* along with the associated domination graph. TARA offers efficient algorithms for offline *EPS* index construction.
- For the rules generated, we design a temporal association rule archive, called *TAR Archive*, that compactly encodes the parameter values of each rule across time. Our specially designed encoding and decoding strategies achieve fast access to the requested information from this archive.
- We propose a rich set of novel temporal rule exploration operations beyond traditional temporal rule mining. Effective strategies for the online processing of the proposed operations that leverage our precomputed TARA index structures are provided.
- TARA framework supports the exploration of the associations at coarser or finer time granularities by roll-up and drill down operations. We provide a theoretical bound on the approximation of the solution under roll-up operations.
- Our extensive experiments using IBM Quest [1], *retail* [3] and *webdocs* [13] datasets demonstrate that **TARA** is 3 to 5 orders of magnitude faster than its state-of-the-art competitors for traditional temporal association mining, while in addition supporting novel analytics within milliseconds.

2. PRELIMINARIES OF TEMPORAL ASSOCIATION

$\mathcal{T} = \{\dots, t_i, \dots, t_j, \dots\}$ denotes a set of **times**, countably infinite, over which a linear order $<_{\mathcal{T}}$ is defined, where $t_i <_{\mathcal{T}} t_j$ means t_i occurs strictly before t_j . Let $\mathcal{I} = \{i_1, i_2, \dots, i_n\}$ represent a set of **items**. $\mathcal{D} = \{d_1, d_2, \dots, d_m\}$ is a collection of subsets of \mathcal{I} called the **transaction database**. Each **transaction** d_i in \mathcal{D} is a set of items such that $d_i \subseteq \mathcal{I}$. Each d_i has an associated timestamp t_j , denoted by $d_i.time = t_j$. Let $\mathcal{X} \subseteq \mathcal{I}$ be a set of items, called **itemset**. If $\mathcal{X} \subseteq d_i$, d_i *contains* \mathcal{X} . If the cardinality of \mathcal{X} is k , \mathcal{X} is called a **k-itemset**. Given a closed **time period** $[t_i, t_j]$ where $t_i <_{\mathcal{T}} t_j$, then the set of transactions in the range $[t_i, t_j]$ of \mathcal{D} that *contain* \mathcal{X} is indicated by $\mathcal{F}(\mathcal{X}, \mathcal{D}, [t_i, t_j]) = \{d_k \mid d_k \in \mathcal{D} \wedge t_i \leq d_k.time \leq t_j \wedge \mathcal{X} \subseteq d_k\}$.

DEFINITION 1. A **temporal association rule** is an expression of the form $\mathcal{R}^{[t_i, t_j]} \equiv (\mathcal{X} \Rightarrow \mathcal{Y})$, where $\mathcal{X} \subseteq \mathcal{I}$, $\mathcal{Y} \subseteq \mathcal{I} \setminus \mathcal{X}$, and $[t_i, t_j]$ indicates that \mathcal{R} is derived from all the transactions in \mathcal{D} whose timestamps fall into $[t_i, t_j]$.

A **temporal association rule** defaults to the traditional association rule if the *time period* is set to the entire timeline. This time restriction $[t_i, t_j]$ empowers the data analysts to discover associations that are not significant throughout the entire data set. Moreover, an association may reappear

Table 1: Example of pregenerated temporal association rule

(a) Item set (min supp = 0.05) (b) Rule (min conf = 0.25)

Itemset	Support		Rule	(Support, Confidence)	
	\mathcal{T}_1	\mathcal{T}_2		\mathcal{T}_1	\mathcal{T}_2
a	0.36	0.44	$\mathcal{R}_1: a \Rightarrow b$	(0.18, 0.5)	(0.11, 0.25)
b	0.45	0.22	$\mathcal{R}_2: b \Rightarrow a$	(0.18, 0.4)	(0.11, 0.5)
c	0.36	0.44	$\mathcal{R}_3: a \Rightarrow c$	(0.18, 0.5)	(0.33, 0.75)
ab	0.18	0.11	$\mathcal{R}_4: c \Rightarrow a$	(0.18, 0.5)	(0.33, 0.75)
ac	0.18	0.33	$\mathcal{R}_5: c \Rightarrow b$	(0.09, 0.25)	(0.11, 0.25)
bc	0.09	0.11	$\mathcal{R}_6: b \Rightarrow c$	-	(0.11, 0.5)

in multiple time periods expressing some periodicity. Furthermore, the association may behave differently in terms of its measured values. The evolution of the associations over time can lead to insightful observations [11].

Many measurements [17] have been proposed to evaluate the interestingness of associations. Out of these measurements, we work with the most common measures of *support* and *confidence* to demonstrate the key principles of our framework, though others can be plugged in the future.

$$Support(\mathcal{R}^{[t_i, t_j]}) = \frac{|\mathcal{F}(\mathcal{X} \cup \mathcal{Y}, \mathcal{D}, [t_i, t_j])|}{|\mathcal{F}(\emptyset, \mathcal{D}, [t_i, t_j])|} \quad (1)$$

$$Confidence(\mathcal{R}^{[t_i, t_j]}) = \frac{|\mathcal{F}(\mathcal{X} \cup \mathcal{Y}, \mathcal{D}, [t_i, t_j])|}{|\mathcal{F}(\mathcal{X}, \mathcal{D}, [t_i, t_j])|} \quad (2)$$

The **support** defined in Formula 1 describes the proportion of the transactions within the defined time period that *contains* all items in the association. The **confidence** defined in Formula 2 describes the probability of finding the **consequent** \mathcal{Y} of the association within the defined time period under the condition that these transactions also *contain* the **antecedent** \mathcal{X} .

3. THE TARA MODEL

We now introduce our **TARA** model framework for interactive exploration of associations from evolving data.

3.1 Time Dimension of the TARA Model

Figure 2: Tumbling Window Model of TARA

Data analysts often are interested in exploring the associations that hold in particular time periods, such as an hour or a day. Coarser time specifications can be broken down to ranges of smaller granularities. Moreover, the measures of an association in a longer time period can then be computed based on the measures of the associations in the shorter periods that are part of this longer period. Based on this observation, **TARA** partitions the data set into disjoint time periods, called *windows*. Mining queries with a coarser time granularity settings than this basic *window size* are then supported using roll-up operations.

Let \mathcal{D} be the evolving data set and w be the basic window

size that represents the minimum granularity. Therefore, the set of *times* \mathcal{T} contains disjoint but consecutive time periods each of size w denoted by $\mathcal{T} = \{\dots, \mathcal{T}_i, \dots, \mathcal{T}_j, \dots\}$, ($\forall \mathcal{T}_i, \mathcal{T}_j$), if $\mathcal{T}_i \neq \mathcal{T}_j$, and $\mathcal{T}_i \cap \mathcal{T}_j = \emptyset$. The evolving data set \mathcal{D} is partitioned into small chunks according to each time period \mathcal{T}_i in \mathcal{T} denoted by $\mathcal{D} = \{\dots, \mathcal{D}_i, \dots, \mathcal{D}_j, \dots\}$ where $\mathcal{D}_i = \mathcal{F}(\emptyset, \mathcal{D}, \mathcal{T}_i)$. In Fig. 2, for example we set the *window size* $w = 20$. That is, the time frame is partitioned into a set of time periods of length 20, e.g. $\mathcal{T}_2 = [t_{21}, t_{40}]$. The evolving data set \mathcal{D} is partitioned into time-oriented data subsets \mathcal{D}_i according to these time periods, e.g. $\mathcal{D}_2 = \mathcal{F}(\emptyset, \mathcal{D}, \mathcal{T}_2)$. For each data partition \mathcal{D}_i , **TARA** pregenerates the associations off-line (See Sec. 4). Table 1.(b) shows an example of the associations generated for the time periods \mathcal{T}_1 and \mathcal{T}_2 . **TARA** processes the raw data \mathcal{D} once to pregenerate the temporal associations held in these windows. A query with the coarser time specification can then be answered based on these pregenerated associations.

DEFINITION 2. Time availability: Let w be the finest time granularity. Then $\mathcal{T}^w = \{\dots, \mathcal{T}_i^w, \dots, \mathcal{T}_j^w, \dots\}$ corresponds to the basic time periods of \mathcal{T} that are generated by **TARA** through time partitioning by w . A time specification \mathcal{T}_k supported in **TARA** thus is $\mathcal{T}_k = \bigcup_{m=i}^j \mathcal{T}_m^w$, where $i \leq j$.

This strategy allows us to support **roll-up** and **drill-down** of time periods at run time such as days, months or years to support long and short term goals.

3.2 Evolving Parameter Space Model

In association rule mining, the input parameter values of *minimum support* and *confidence* can be any real number within $[0,1]$. Each combination, referred to as **parameter setting**, corresponds to a set of rules generated by using this parameter setting. We now extend this into the notion of an *Evolving Parameter Space (EPS)* that models relationships and distribution of rules across the multi-dimensional temporal parameter space.

Figure 3: Evolving Parameter Space

DEFINITION 3. Evolving Parameter Space: Let \mathcal{D} be an evolving data set, \mathcal{D}_i be a *partition* of \mathcal{D} by a basic time granularity \mathcal{T}_i , $\forall \mathcal{T}_i \in \mathcal{T}$. Let p_j be one of the n parameters. The $(n+1)$ -dimensional space, denoted by $\mathcal{E} = \{p_1, \dots, p_n, \mathcal{T}\}$ and called **Evolving Parameter Space (EPS)**, organizes the rules $\{\mathcal{R}\}^{\mathcal{T}}$ where $\{\mathcal{R}\}^{\mathcal{T}} = \bigcup_{i=1}^k \{\mathcal{R}\}^{\mathcal{T}_i}$ and k is the

total number of time partitions of \mathcal{D} . A temporal association rule \mathcal{R} is associated with its **temporal parametric locations** $(\mathcal{R}.value(p_1), \dots, \mathcal{R}.value(p_n))^{\mathcal{T}_i}$ where $\mathcal{R}.value(p_j)$ denotes the value of the j^{th} parameter for rule \mathcal{R} in time \mathcal{T}_i .

For simplicity, we use two parameters, namely *support* and *confidence* while others could be defined as well. Thus henceforth, the EPS \mathcal{E} is a 3-dimensional space with *support*, *confidence* and *time* as its dimensions. A *temporal parametric location* depicting a rule \mathcal{R} in time \mathcal{T}_i , denoted as $\mathcal{R}(supp, conf)^{\mathcal{T}_i}$, is represented as a line segment indicating the parameter values of \mathcal{R} in \mathcal{T}_i . Fig. 3 shows the EPS for the rules in Table 1.(b). Rules $\mathcal{R}_1, \mathcal{R}_3$ and \mathcal{R}_4 map to the same *temporal parametric location* $(0.18, 0.5)^{\mathcal{T}_1}$ in the time period \mathcal{T}_1 . However in time \mathcal{T}_2 , \mathcal{R}_1 travels in the space so that now it maps to same location as $\mathcal{R}_5(0.11, 0.5)^{\mathcal{T}_2}$.

Figure 4: Evolving Parameter Space slice at Time \mathcal{T}_2

LEMMA 3.1. Let \mathcal{L} denote a temporal parametric location in the EPS \mathcal{E} , $\mathcal{L}.p_i$ be the value of parameter p_i for location \mathcal{L} . Given a set of temporal parametric locations in the same time period \mathcal{T}_i , $\forall \mathcal{L}_m, \mathcal{L}_n \in \{\mathcal{L}\}$, where $m \neq n$, if there exists a p_i such that $\mathcal{L}_m.p_i \neq \mathcal{L}_n.p_i$, then the temporal association rules that map to \mathcal{L}_m are guaranteed to be distinct from those that map to \mathcal{L}_n .

PROOF. Rules' temporal parametric locations in time \mathcal{T}_i are generated from the same data partition \mathcal{D}_i . Any given rule at time \mathcal{T}_i cannot have two distinct values for one parameter. Therefore, a rule \mathcal{R} cannot map to two distinct temporal parametric locations within the same time. \square

Each rule's temporal parametric location can either remain steady or change over multiple time periods. We call this stream of locations the **trajectory of the association**.

DEFINITION 4. Trajectory of an association: Given a sequence of time periods $\{\mathcal{T}\} = \{\mathcal{T}_1, \dots, \mathcal{T}_m\}$, the **trajectory of an association** \mathcal{R} in $\{\mathcal{T}\}$ is the set of temporal parametric locations that represent its parameter values in the time periods in $\{\mathcal{T}\}$.

This trajectory of a rule allows us to compute different measures about the rule that summarize its evolving patterns like *coverage* [16], *stability* [11] and *standard deviation*. These measures can be computed for each individual rule or even for a set of rules to provide individual or global summarization respectively.

Given a data set with n unique items, the maximum number of rules is finite, bounded by $3^n - 2^n + 1$ [10]. Therefore, some set of parameter settings must correspond to same set

of rules. Fig. 4 shows a slice of the evolving parameter space for time \mathcal{T}_2 . Rules with identical parameter values are represented by the same point in this space. These points partition the space into 4 regions marked by dashed lines. If a user specified *minimum support* and *confidence* configuration for mining falls into region \mathcal{S}_3 , then regardless of its actual position within the region, the output ruleset is always $\{\mathcal{R}_3, \mathcal{R}_4\}$. This observation is inspired by the work presented in [10]. Thus the entire evolving parameter space at a time \mathcal{T}_i can be partitioned into a finite set of regions referred to as *time-aware stable regions*. This notion of *time-aware stable regions* forms our coarse granularity abstraction of the temporal association rules generated from an evolving data set \mathcal{D} .

DEFINITION 5. Time-Aware Stable Regions: Given an EPS \mathcal{E} of n parameters $\{p_1, \dots, p_n\}$ and times \mathcal{T} as $(n+1)$ dimensions for an evolving data set \mathcal{D} , then a **time-aware stable region** in a time period \mathcal{T}_i is a closed hyper-box denoted by $\mathcal{S}_{\mathcal{T}_i}^{(upper(p_1), \dots, upper(p_n))}$ with its boundary specified by locations $(\mathcal{S}.upper(p_1), \dots, \mathcal{S}.upper(p_n))^{\mathcal{T}_i}$ and $\{(\mathcal{S}.lower(p_1), \dots, \mathcal{S}.lower(p_n))^{\mathcal{T}_i}\}$ within each of which no matter how the parameter values are adjusted, the set of rules generated from \mathcal{D}_i remains unchanged.

Considering the 3-dimensional EPS in Fig. 3, a *time-aware stable region* is bounded by an upper location $(supp_u, conf_u)^{\mathcal{T}_i}$ and k lower locations $\{(supp_{l_j}, conf_{l_j})^{\mathcal{T}_i}\}$ where $j \in [1, k]$. The *support* and *confidence* values of the upper location will always be greater than those of all its lower points, i.e., $\forall j (supp_u \geq supp_{l_j})$ and $(conf_u \geq conf_{l_j})$. The upper location of a *time-aware stable region* is called its **cut location**.

DEFINITION 6. Cut Location: Let EPS \mathcal{E} be a 3-dimensional space with support x , confidence y and time z as its dimensions, $\{\mathcal{X}\}$ be a set of the intersections formed by the perpendicular projections of each temporal parametric location onto x and y planes. The cut locations within \mathcal{E} are then denoted by $\{\mathcal{C}\}$, where $\{\mathcal{X}\} = \{\mathcal{C}\} \cup \{\mathcal{L}\}$.

Fig. 3 depicts *time-aware stable regions* $\mathcal{S}_{\mathcal{T}_1}^{(0.18, 0.5)}$ and $\mathcal{S}_{\mathcal{T}_2}^{(0.11, 0.5)}$. For region $\mathcal{S}_{\mathcal{T}_1}^{(0.18, 0.5)}$, the cut location is $(0.18, 0.5)^{\mathcal{T}_1}$. It is bounded by the parametric locations $(0.18, 0.5)^{\mathcal{T}_1}$ and $(0, 0.4)^{\mathcal{T}_1}$ and contains rules $\mathcal{R}_1, \mathcal{R}_3$ and \mathcal{R}_4 .

LEMMA 3.2. Given a set of time-aware stable regions $\{\mathcal{S}\}$ for the same \mathcal{T}_i , $\forall \mathcal{S}_m, \mathcal{S}_n \in \{\mathcal{S}\}$, where $m \neq n$, the associations that map to the cut location of \mathcal{S}_m are guaranteed to be distinct from the ones that map to the cut location of \mathcal{S}_n .

PROOF. By Lemma 3.1, rules generated in the same time period but map to different *temporal parametric locations* are guaranteed to be distinct. The locations in $\{\mathcal{X}\}$ either belong to $\{\mathcal{L}\}$ or have no rule. Therefore, within a time period \mathcal{T}_i , rules that map to different *time-aware stable regions* are guaranteed to be distinct. \square

DEFINITION 7. Dominating Stable Region: A time-aware stable region \mathcal{S}_m **dominates** region \mathcal{S}_n where $m \neq n$, if and only if $\forall p_i \in \mathcal{P} \mathcal{S}_m.C.p_i \leq \mathcal{S}_n.C.p_i$, and \mathcal{S}_m and \mathcal{S}_n are in same \mathcal{T}_i where $\mathcal{S}_m.C$ refers to the cut location of stable region \mathcal{S}_m .

LEMMA 3.3. Considering two time-aware stable regions \mathcal{S}_m and \mathcal{S}_n where $m \neq n$. If \mathcal{S}_m dominates \mathcal{S}_n , then rules valid within the dominated region \mathcal{S}_n are also valid in the dominating region \mathcal{S}_m but not vice versa.

PROOF. A temporal rule \mathcal{R}_i is in the final output ruleset if in the specified \mathcal{T}_k , $\forall p_j, \mathcal{R}_i.value(p_j) \geq \min parameters$ where $p_j \in \{p_1, \dots, p_n\}$. If \mathcal{R}_i belongs to region \mathcal{S}_n , the *temporal parametric location* of \mathcal{R}_i is the upper location of \mathcal{S}_n . Because \mathcal{S}_m dominates \mathcal{S}_n , $\forall p_j, \mathcal{S}_m.upper(p_j) \leq \mathcal{S}_n.upper(p_j)$, meaning $\forall p_j, \mathcal{S}_m.upper(p_j) \leq \mathcal{R}_i.value(p_j)$. So \mathcal{R}_i is valid in \mathcal{S}_m as well. However, vice versa is not true, as can be trivially shown. \square

Consider $\mathcal{S}_1 = \mathcal{S}_{\mathcal{T}_1}^{(0.18, 0.5)}$ and $\mathcal{S}_2 = \mathcal{S}_{\mathcal{T}_1}^{(0.09, 0.25)}$ in Fig 3. Based on Def. 7, \mathcal{S}_2 dominates \mathcal{S}_1 because every parameter value in the upper location of \mathcal{S}_2 is smaller than the corresponding value of \mathcal{S}_1 .

If the rules in region $\mathcal{S}_{\mathcal{T}_1}^{(0.09, 0.25)}$ are included in the final result, then region must also contain the rules that are valid in $\mathcal{S}_{\mathcal{T}_1}^{(0.18, 0.5)}$. By Lemma 3.3, given a user-specified parameter setting, once a region is identified as a valid region to produce the final ruleset, all its dominated regions should then also be included in the user output.

Using this concept of dominating stable regions [10], each rule is stored once in the stable region and by iterating over its dominating regions the final ruleset can simply be obtained for a given pair of *support* and *confidence* values.

3.3 Supported Queries on TARA Model

We now propose TARA operations that offer a rich classes of novel temporal analytical queries.

Temporal Association Mining. Given a parameter setting and time periods, $Q1$ returns the associations that satisfy the minimum parameters, such as *minimum support* and *confidence*. The evolving trajectory and measures of associations for each of the specified time periods are also returned. The Measures including *coverage* [16], *stability* [11] and *standard deviation* summarize the evolving patterns. *Exact match* option returns the associations that are consistently valid in *all* of the specified time periods. *Single match* returns the associations that are valid in exactly one of the specified time periods. *Fuzzy match* returns the associations that are valid in *at least* one or more of the specified time periods. $Q2$ returns the differences of associations with regards to two different parameter settings.

```
Q1 RETURN Rule, Trajectory, Measures
FROM Evolving Data Set D
PARAMETER  $\bigwedge_{i=1}^n \text{MinParameter}_i = P_i$ 
IN-TIME = Time Periods & Granularity
MATCH = Exact|Single(Time Period)|Fuzzy
```

Use Case for Temporal Association Mining. In the retail dataset [3], over the time period of one year broken in windows of a week, $Q1$ may return the rule (*turkey* \implies *pumpkin pie*) with relatively low support and confidence value (0.4, 0.5) throughout the year. However, this rule periodically rises to high support and confidence value of (0.6, 0.7) in the week before *Thanksgiving*. If we had examined this rule in the roll-up view over the complete data (whole year), it's support and confidence would overall have been too low. With $Q1$, an analyst can find the rules that are frequent

only within certain intervals. It also allows to find all time periods during which this rule was more popular.

Q2 RETURN Rule, Trajectory, Measures
 FROM EPS E
 PARAMETER $\bigwedge_{i=1}^n \text{MinParameter}_i = P1_i$
 COMPARE-TO $\bigwedge_{i=1}^n \text{MinParameter}_i = P2_i$
 IN-TIME = Time Periods & Granularity
 MATCH = Exact|Single(Time Period)|Fuzzy

Use Case of Unnoticeable Changes. For a dense data set like webdocs [13], the size of the returned rulesets is huge, making it difficult for the analysts to perform manual inspection of the differences produced by two different parameter settings. To effectively tune the best parameter setting that includes the most important associations across the specified time intervals, analyst would benefit from being able to quickly explore the differences in the results. $Q2$ allow to find all rules that were generated in last month by parameter configuration setting like (0.4, 0.8) but not by configuration setting (0.5, 0.95).

Stable Region Exploration. These queries provide meta information about the *time-aware stable regions*. In particular, $Q3$ returns the sets of stable regions identified for the given parameter settings across the time periods specified by the *match* clause. $Q4$ returns region parameters that contain the specified associations.

Q3 RETURN Stable Region
 FROM EPS E
 PARAMETER $\bigwedge_{i=1}^n \text{MinParameter}_i = P_i$
 IN-TIME = Time Periods & Granularity
 MATCH = Exact|Single(Time Period)|Fuzzy

Use Case of Parameter Recommendation. For a sparse dataset like retail [3], often despite submitting several successive mining requests with different parameter settings, the system repeatedly returns the same set of rules due to a sparse distribution of rules. This trial and error process can be avoided by using query $Q3$. For example for the retail dataset [3] broken in windows of a week, $Q3$ can easily inform an analyst that during the last week of a month, the same set of rules will be generated for all parameter configurations within (0.88, 0.76) and (0.91, 0.78).

Q4 RETURN Region
 FROM Ruleset $\bigcup_{i=1}^n R_i$
 IN-TIME = Time Periods & Granularity
 MATCH = Exact|Single(Time Period)|Fuzzy

Time Specification: Roll-up and Drill-down. For each of the above queries, a time granularity must be specified. For example, a time period \mathcal{T}_i can refer to a particular *hour*, a *day*, or a *week*.

Rule Search. As [12] pointed out, supporting content-based rule search can leverage analysts' domain knowledge to efficiently narrow down the result into a more manageable smaller set. $Q5$ allows analysts to filter a ruleset, generated by any of the above queries, based on the absence or presence of certain *items* given in the MATCH clause.

Q5 RETURN Rule
 FROM Ruleset $\bigcup_{i=1}^n R_i$
 MATCH $\{I\}^+ \cup \{I\}^-$

Use Case of Content-based Association Exploration. In the retail dataset using query $Q1$ with *Single match* option and the time equal to week before *Christmas* returns a huge number of rules for the support and confidence values of (0.4, 0.5). With $Q5$ an analyst can quickly find all the rules that contains "*Ipads*" and do not include "*Laptops*".

4. OFF-LINE EPS-INDEX CONSTRUCTION

Our proposed *Evolving Parameter Space* (EPS) Index construction is composed of three tasks that are performed offline. Task 1 generates the temporal association rules; task 2 computes the *time-aware stable regions* and constructs the domination graph, and task 3 constructs the *EPS-Index*. These tasks three are explained below (See Algo. 1).

Task 1: Temporal Association Rule Generation. **TARA** first pre-generates the rules from the evolving dataset using the lowest meaningful parameter settings, called the *primary support* θ and the *confidence* λ , to prevent excess pre-generation [12]. Based on the *minimum time granularity*, **TARA** mines the rules from the current window, whose *support* and *confidence* value exceed θ and λ . The rules and their parameter values w.r.t to the transactions within this window are then archived (See Sec. 5). In our work, we plug in FP-Tree [7] as the rule generation algorithm. The rule mining module in **TARA** framework is extendable to any incremental or parallel rule mining solution [8].

Task 2: Time-Aware Stable Region. To construct the *time-aware stable regions* (see Def. 5), **TARA** first computes the *cut locations* using a two step approach. In the first step, the *temporal parametric locations* of rules generated in the previous task are initialized as the first set of *cut locations*. Each *cut location* maintains a set of references to its rules. In the second step, let x , y , and z be the axes representing *support*, *confidence* and *time* measures and o be the origin of all measures. The intersections formed by the perpendicular projections of each point onto the x and y planes are added to the *cut location* set.

By Lemma 3.2, each *cut location* identifies a unique *time-aware stable region*. For each *cut location*, the lower bounds are computed to form a complete *time-aware stable region*. Simultaneously, the *immediate dominated regions* are identified and connected to construct the domination graph. Upon user request, the *time-aware stable regions* can be constructed for the coarser time granularity over basic granularity used by the system. New parameter values of rules forming these *time-aware stable regions* are computed by Formulas 4 & 5.

Task 3: EPS-Index Construction. Within each *time-aware stable region*, all rules are indexed by their respective attributes, called a *region shard*. Next, the two layered *Evolving Parameter Space Index* (*EPS-Index*) is created to efficiently answer the **TARA** model requests. The top level of the *EPS-Index* facilitates the search to locate a particular *time-aware stable region* given its input parameters. Regions are indexed separately by different time periods. For regions within a single time period, a grid-based spatial index is utilized to partition the EPS into equal-sized grid cells. The time-aware stable regions are then allocated to their respective positions in the grid. The stable regions in

  begin
    GridIndexer( $\{\mathcal{S}\}$ );

```

Figure 5: The EPS-Index

each cell point to the corresponding nodes in the next level of the *EPS-Index*. Fig. 5 shows the spatial index of the *time-aware stable regions* for \mathcal{T}_1 .

Using the proposed grid structure, the online search for a stable region can be performed in near constant time. The online processing of our **TARA** exploration using this index is described in Sec. 7.

The second level of the *EPS-Index*, namely, the region domination graph (Fig. 5), is designed to expedite the collection of rules from dominating regions [10]. Each stable region forms a node in the graph with each node linked to its closest dominating neighbors. The region domination graph enables us to locate the closest dominating neighbor regions in near constant time and also produce complete rule sets in linear time in the number of rules involved.

5. TEMPORAL ASSOCIATION ARCHIVE

As explained before, the rules themselves can be huge. We describe an efficient storage structure for managing the rules generated across time called temporal association rule archive (*TAR Archive*).

5.1 TAR Archive Design

Our proposed archive structure consists of a directory and a number of index entries. The directory contains all temporal association rules. Each rule in the directory has a pointer to its index entry. The index entry stores the history of its parameters w.r.t a specific time granularity. The index entry can be implemented using a *time sequence* [6] as illustrated in Fig. 6. For simplicity only one parameter is shown. The size of the *time sequence* is equal to the number of basic windows. The advantage of using such naive *time sequence* is that every element in this structure maps to a parameter value of the rule within a specific window. Given a window and rule id, the search of the parameter value takes only $O(1)$ time.

Rule Directory	\mathcal{T}_1	\mathcal{T}_2	\mathcal{T}_3	\mathcal{T}_4
R_1	0.5	0.5	0.5	0.6
R_2	0.4	0.3	0.3	0.3
R_3	0.6	0.6	0.4	0.5
R_4	0.5	0.3	0.2	0.3
R_5	0.7	0.0	0.0	0.0
R_6	0.0	0.0	0.0	0.8

Figure 6: Rule Index with Time Sequence

Interestingly, [15] observed that daily updates in transaction databases more often than not affect only a small part of the ruleset. [6] also indicates that parameter values of the frequent patterns mined from the data stream often remain stable within a period of time. In Fig. 6, R_1, R_2 and R_3 are stable over several consecutive windows. Therefore, the time sequence structure may contain redundant values.

Rule Directory	Binary Encoding	Compressed Entry
R_1	1001(9)	0.5 0.6
R_2	11(3)	0.4 0.3
R_3	1101(13)	0.6 0.4 0.5
R_4	1111(15)	0.5 0.3 0.2 0.3
R_5	11(3)	0.7 0.0
R_6	1001(9)	0.0 0.8

Figure 7: Rule Index with Compact Time Sequence

To avoid the above problems while still achieving efficient access, we propose the *TAR Archive* with *compact time sequence* structure as depicted in Fig. 7. Each *compact time sequence* for one parameter consists of a binary code \mathcal{B} and an array of distinct parameter values, called *value sequence*, denoted as $\mathcal{V} = \{v_1, \dots, v_n\}$. The i th bit from the lowest order indicates whether or not the parameter value within the i th window is identical to the value within the previous window. The encoding strategy is shown in Formula 3.

$$\text{Bit}(\mathcal{R}.p_i^j) = \begin{cases} 0 & \text{if } \mathcal{R}.p_i^j = \mathcal{R}.p_i^{j-1} \\ 1 & \text{otherwise} \end{cases} \quad (3)$$

For example, in Fig. 6 the parameter values of R_1 are stable in the first three windows with only the value in the latest window being different. “1001” denotes the evolution of this parameter across 4 windows. The lowest order digit represents the parameter value in the oldest window and the highest order digit represents the parameter value in the newest window. In this case, the parameter values in $\mathcal{T}_1, \mathcal{T}_2$

and \mathcal{T}_3 only need to be stored once in the structure because they are identical.

5.2 TAR Archive Operations

Next we discuss the supported operations, namely *append*, *access*, *purge* and *merge* on the *TAR Archive*.

Append: As the new window is being processed, rules are added into the *TAR Archive*. We distinguish between three cases when a rule is being appended: (1) The new rule already exists in the archive; (2) The new rule does not exist in the archive; (3) A rule that is in the archive does no longer appear in the newly generated ruleset.

For case 1, if the new value of the rule is different than in the last window, then “1” is added to the binary code otherwise no action is needed. To address case 2, first, this new rule is inserted in the rule directory. Second, for each parameter, if the current window is the very first window, the binary code is set to “1” and p_i^0 is inserted into the empty *value sequence*. If $j > 0$, the binary code is first initialized as “1” and “0.0” is inserted into the value sequence. Then the procedure in case 1 is followed to process the new information. To address case 3, the system simply appends the parameter value “0.0” to all parameters of such rule. The append procedure is the same as the procedure for case 1.

Access: Our decoding strategy for *compact time sequence* structure allows to search *TAR Archive* takes $O(1)$ time. Given a window id j , the parameter value p_i^j from \mathcal{V}_i is retrieved. For instance, in Fig. 7, for \mathcal{R}_1 , if $j = 3$, the system needs to locate the correct value p^3 in the value sequence. In B_i , the count of “1” is the length of the value sequence because every time a bit is set to “1”, a new value is then appended to the *value sequence*. Finding the offset of the element in the sequence value corresponding to the queried window j is equivalent to counting “1”s up until the j th bit in B_i . For the previous example, if $j = 3$, the binary code up until 3rd bit in B is “001” which only has 1 bit set to “1”. So s_1 in the value sequence represents the value of p^3 . Given a j , we calculate the offset of the element in the *value sequence* as follows $Offset(j) = HammingWeight(B \text{ AND } (2^j - 1))$. $HammingWeight$ is a $O(1)$ algorithm for bit counting.

Purge: As parameter values begin to accumulate, the size of the archive grows bigger and bigger. For some applications, historical information inserted at the very beginning may become insignificant. Therefore, an operation that purges such data is necessary. Specifically, the operator deletes the parameter values of the entire ruleset in the archive w.r.t a set of consecutive windows from \mathcal{T}_1 to \mathcal{T}_k where $k \leq \text{total number of windows}$. For each rule R , the purge operation performs a two-step procedure: (1) Delete the values that correspond to $\langle \mathcal{D}_1, \dots, \mathcal{D}_k \rangle$ for each parameter from the *value sequence*. (2) Update the binary code so that it reflects the changes of the parameter within the rest of the windows. For an input k , if $Offset(k)$ equals to $Offset(k+1)$ which means the values of a parameter in \mathcal{D}_k and \mathcal{D}_{k+1} are mapped to the same s_i in S , then $\{s_j | 1 \leq j \leq i-1\}$ are removed from S . The corresponding B is right shifted $i-1$ times and the first bit of the modified B' is set to “1”. If the results of $Offset(k)$ and $Offset(k+1)$ are not identical, then $\{s_j | 1 \leq j \leq i, i = Offset(k)\}$ are removed from S . The corresponding B vector is right shifted i times.

Merge: For some applications, analysts may be interested in recent changes at a fine granularity, but longer term changes at a coarse granularity. To support such time-sensitive roll-

up, also called *Natural tilted-time window* or *logarithmic tilted-time window* [6] an efficient merge operation is needed for the *TAR Archive*.

$\{\mathcal{R}\}_i$ denotes the ruleset generated from \mathcal{D}_i . The merge operation unions the rulesets, $\bigcup_{w=i}^j \{\mathcal{R}\}_w$, that correspond to the set of consecutive windows $[\mathcal{T}_i, \mathcal{T}_j]$ and computes the new parameter value for each rule in the merged window. $[\mathcal{T}_i, \mathcal{T}_j]$ denotes a set of consecutive windows that are requested to be merged, $|\mathcal{D}_j|$ denotes the total number of transactions in \mathcal{T}_j . The *support* and *confidence* of a rule in the merged window is computed as follows:

$$Support(\mathcal{R}) = \frac{\sum_{w=i}^j |\mathcal{D}_w| \times \mathcal{R}.supp^w}{\sum_{w=i}^j |\mathcal{D}_w|} \quad (4)$$

$$Confidence(\mathcal{R}) = \frac{\sum_{w=i}^j |\mathcal{D}_w| \times \mathcal{R}.supp^w}{\sum_{w=i}^j |\mathcal{D}_w| \times \frac{\mathcal{R}.supp^w}{\mathcal{R}.conf^w}} \quad (5)$$

Based on the definition of *support* and *confidence*, Formula 4 describes the proportion of the transactions within the merged window that *contains* all items of the association; Formula 5 describes the ratio of the number of the transactions that *contains* all items of the association to the number of the transactions that *contains* antecedent items in the merged window. With these new values, the merge operator then further updates both the binary encodings \mathcal{B}_i and value sequences \mathcal{V}_i in the rule entry. For a particular parameter of a rule, if the windows from i to j are merged, then the bits from i th to j th position in its binary code are also merged into one bit. The value of this new bit and $(i+1)$ th bit depends on whether the represented parameter value is different from its last parameter value. For example, in Fig. 7 when \mathcal{T}_2 and \mathcal{T}_3 are requested to be merged, the new binary code becomes “11” and value is 0.3.

6. ROLL-UP SUPPORT ACROSS TIME

In the rule generation step, rules with parameter values below minimal system thresholds are not maintained. Therefore, we may not have the exact parameter values for each rule when multiple windows are merged. The parameter value of a rule in a coarser time period (merged window) is computed based on its parameter values in all periods that compose the window. The calculation is described in Formula 4 & 5. For example, let θ be 0.1, support values of \mathcal{R} in \mathcal{T}_1 and \mathcal{T}_2 be 0.2 and 0.08 respectively. If \mathcal{T}_1 and \mathcal{T}_2 are requested to be merged, the exact *support* of R in the new window is $\frac{|\mathcal{D}_1| \times 0.2 + |\mathcal{D}_2| \times 0.08}{|\mathcal{D}_1| + |\mathcal{D}_2|}$. However, let us assume that R had been withdrawn from \mathcal{T}_2 because $0.08 < \theta$. Therefore the *support* value of R in \mathcal{T}_2 becomes unknown and thus is treated as 0. As a result, we no longer have the exact parameter value of rules in a merged coarser-time-granularity window, rather only an approximate value. Rules withdrawn from a window may fall into 3 cases depending on whether they either fail to satisfy one of the system thresholds or both. The margin of error of the parameters value in merged windows varies case by case. Since the withdrawn rules are absent from the system, the exact reason of the withdrawal becomes unknown. Therefore, we introduce the worst sce-

nario below:

Let $[\mathcal{T}_i, \mathcal{T}_j]$ be a set of consecutive windows that are requested to be merged, \mathcal{R} be a rule that at least appears once in any of these windows, \mathcal{T}' be the windows in which \mathcal{R} is absent, \mathcal{T}'' be the windows in which \mathcal{R} appears, $S(\mathcal{R})$ and $C(\mathcal{R})$ be the approximated *support* and *confidence* of \mathcal{R} calculated based on Formulas 4&5, $\hat{S}(\mathcal{R})$ and $\hat{C}(\mathcal{R})$ be the exact *support* and *confidence* of \mathcal{R} . The worst scenario arises where all absents of \mathcal{R} are caused by $\mathcal{R}.supp \geq \theta$ and $\mathcal{R}.conf < \lambda$.

In this case, \mathcal{R} has a qualified *support*. In order to have a *confidence* value smaller than the threshold, \mathcal{R} 's *support* must be larger than θ , however, smaller than λ . Therefore,

$$S(\mathcal{R}) \leq \hat{S}(\mathcal{R}) \leq \frac{\sum_{k=1}^m |\mathcal{D}'_k| \times \lambda + \sum_{k=1}^n |\mathcal{D}''_k| \times \mathcal{R}.supp_{\mathcal{D}''_k}}{\sum_{w=i}^j |\mathcal{D}_w|} \quad (6)$$

The error in confidence is caused by miss counting the withdrawn *support* of \mathcal{R} , as well as miss counting of the withdrawn *support* of the antecedent of \mathcal{R} . The *confidence* with maximum margin of errors is the following:

$$margin = \frac{\sum_{k=1}^m |\mathcal{D}'_k| \times \lambda + \sum_{k=1}^n |\mathcal{D}''_k| \times \mathcal{R}.supp_{\mathcal{D}''_k}}{\sum_{k=1}^m |\mathcal{D}'_k| + \sum_{k=1}^n |\mathcal{D}''_k| \times \frac{\mathcal{R}.supp_{\mathcal{D}''_k}}{\mathcal{R}.conf_{\mathcal{D}''_k}}} \quad (7)$$

Note that this value does not guarantee to be smaller or larger than $\hat{C}(\mathcal{R})$, because the errors are both introduced in the numerator and denominator.

Formula 6 gives the worst scenario for the approximation of *support* and Formula 7 the worst scenario for the approximation of *confidence*. The smaller θ and λ are, the more accurate our approximation will be. Because with a smaller system threshold, less rules would be withdrawn from the window reducing the chance of miss counting.

7. ONLINE QUERY PROCESSING

In this section, we explain how the analytical TARA queries introduced in Section 3 are handled by the **TARA** framework (Algo. 2). Depending upon the query type, the appropriate subroutine is invoked. $Q1$, $Q2$ and $Q3$ are handled by subroutines 2.A, 2.B, 2.C respectively. For $Q4$ once the ruleset is selected by any of the subroutines, routine 2.C is used to return the stable region.

The **response time** for query processing mainly consists of 3 components, namely, $Cost(SearchRegion)$, $Cost(GetRule)$ and $Cost(GetDominatedRegions)$. The TARA storage structures namely *EPS-Index* and *TAR Archive* are in-memory structures. The cost for a region search against *EPS-Index* is $\mathcal{O}(1)$. As illustrated in Fig. 5, locating the regions within the same time interval takes $\mathcal{O}(1)$. By converting input parameters into offsets, the appropriate cell can be found in $\mathcal{O}(1)$ as well. Thus $Cost(SearchRegion) = \mathcal{O}(1)$. Note that the system must generate the stable regions for such time periods in which they don't exist. To iteratively collect all the immediate dominated regions in the domination graph, a breadth-first search (BFS) is required starting at the node containing $(minsupp, minconf)$ in \mathcal{T} . The time complexity of BFS is $\mathcal{O}(|V| + |E|)$. In our case, $E \leq (2 \times V)$ as each vertex has a fanout of at most two edges. Thus,

Algorithm 2: Online Temporal Association Exploration

2.A: Temporal Association Mining Query

Input: $s, c, \{\mathcal{T}\}, matchtype$

Output: Ruleset

```

begin
   $\{\mathcal{R}\} \leftarrow \emptyset; \{\mathcal{S}\} \leftarrow \emptyset;$ 
  switch matchtype do
    case single( $\mathcal{T}$ )
       $\{\mathcal{S}\} \leftarrow SearchRegion(s, c, \mathcal{T});$ 
       $\{\mathcal{S}\} \leftarrow \{\mathcal{S}\} \cup GetDominatedRegion(\{\mathcal{S}\});$ 
    case exact
       $\mathcal{T} \leftarrow \text{any } \mathcal{T} \in \{\mathcal{T}\};$ 
       $\{\mathcal{S}\} \leftarrow SearchRegion(s, c, \mathcal{T});$ 
       $\{\mathcal{S}\} \leftarrow \{\mathcal{S}\} \cup GetDominatedRegion(\{\mathcal{S}\});$ 
    case fuzzy
      for each  $\mathcal{T}_i \in \{\mathcal{T}\}$  do
         $\{\mathcal{S}\} \leftarrow SearchRegion(s, c, \mathcal{T}_i);$ 
         $\{\mathcal{S}\} \leftarrow \{\mathcal{S}\} \cup GetDominatedRegion(\{\mathcal{S}\});$ 
   $\{\mathcal{R}\} \leftarrow GetRule(\{\mathcal{S}\});$ 

```

2.B Ruleset Comparison Query

Input: $s_1, c_1, s_2, c_2, \mathcal{T}, matchtype$

Output: Rulesets $\{\mathcal{R}\}_1, \{\mathcal{R}\}_2$

```

begin
   $s_c \leftarrow \max(s_1, s_2); c_c \leftarrow \max(c_1, c_2);$ 
   $\{\mathcal{S}\}_1 \leftarrow SearchRegion(s_1, c_1, \mathcal{T});$ 
   $\{\mathcal{S}\}_2 \leftarrow SearchRegion(s_2, c_2, \mathcal{T});$ 
  //Collect the regions till it reaches a parameter value
  for  $i = 1; i \leq 2; i++$  do
    if  $s_i \neq s_c$  then
       $\{\mathcal{S}\}_i \leftarrow GetDominatedRegion(\mathcal{S}_i, s_c);$ 
    if  $c_i \neq c_c$  then
       $\{\mathcal{S}\}_i \leftarrow GetDominatedRegion(\mathcal{S}_i, c_c);$ 
   $\{\mathcal{R}\}_1 \leftarrow GetRule(\{\mathcal{S}\}_1);$ 
   $\{\mathcal{R}\}_2 \leftarrow GetRule(\{\mathcal{S}\}_2);$ 

```

2.C Stable Region Query

Input: $s, c, \{\mathcal{T}\}, matchtype$

Output: Region \mathcal{S}

```

begin
   $\{\mathcal{S}\} \leftarrow \emptyset;$ 
  switch matchtype do
    case single( $\mathcal{T}$ )
       $\mathcal{S} \leftarrow SearchRegion(s, c, \mathcal{T});$ 
    case exact or fuzzy
      for each  $\mathcal{T}_i \in \{\mathcal{T}\}$  do
         $\{\mathcal{S}\} \leftarrow SearchRegion(s, c, \mathcal{T}_i);$ 

```

$Cost(GetDominatedRegions) = \mathcal{O}(|V|)$. If the trajectory of a rule cannot be obtained from the retrieved regions (*exact* or *single* match), $GetRule$ searches the parameter values of the rule in the specified periods in the *TAR Archive*. If the granularity of the specified time periods is coarser than the ones available in the archive, $GetRule$ finds the windows that are contained in coarser time periods and computes the parameter value for the merged window. See Sec. 5 for the complexity analysis of accessing the *TAR Archive* and the computation for obtaining the parameter value in the merged window.

8. EXPERIMENTAL EVALUATION

Experimental Setup. Experiments are conducted on a OS X machine with 2.4 GHz Intel Core i5 processor and 8 GB RAM. The system and its competitors are implemented in C++ using Qt Creator with Clang 64-bit compiler.

Datasets. We select a variety of datasets with diverse characteristics here. The benchmark datasets, *T5kL50N100* and *T2kL100N1k*, are generated by the *IBM Quest data generator* [1] modeling transactions in a retail store. We

Table 2: Datasets

	<i>100retail</i>	<i>T5k</i>	<i>T2k</i>	<i>webdocs</i>
Transactions	8,816,200	5,000,000	2,000,000	1,692,082
Unique Items	16,470	23,870	30,551	5,267,656
Avg Len of Tran	10	50	100	177
Size	416.8 MB	1.48 GB	1.38 GB	1.48 GB

Table 3: Thresholds for Indexes

Dataset	H-Mine	TARA&PARAS (supp, conf)
retail	0.0002	(0.0002, 0.1)
T5k	0.0012	(0.0012, 0.2)
T2k	0.001	(0.001, 0.2)
webdocs	0.1123	(0.1123, 0.2)

partition these datasets into 5 equal-sized batches to form the evolving data sources. The *retail* dataset [3] contains 88,163 transactions collected from a Belgian retail supermarket store in 5 months. To study scalability, we replicate this *retail* dataset 100 times. The *webdocs* dataset [13] is built from a spidered collection of web html documents. Both of these real datasets are partitioned into 10 equal-sized batches to form evolving data sources. The statistics of the datasets are summarized in Tab. 2.

Alternate State-of-the-art Techniques. The performance of **TARA** is compared against three competitors. **DCTAR** [9] derives the ruleset directly from the raw data given a parameter configuration. It computes the associations from scratch whenever a new batch of data arrives. **H-Mine** [18] instead pregenerates the intermediate frequent item sets offline. For specific parameter settings, the algorithm utilizes the itemsets to generate the associations online instead of extracting them from the raw data. **PARAS** [10] pregenerates frequent itemsets and rules offline for the entire data set assuming all data is static and given apriori. That is, time is ignored. For our experiments, we construct the **PARAS** index for a single time period. However at online time if request comes for different periods it then generates the associations from scratch.

Experimental Methodologies: The performance of our approach and state-of-the-art algorithms is measured by:

Offline Preprocessing Time. We measure the single and multiple data batches preprocessing time for **TARA**, **H-Mine** and **PARAS**. Since **DCTAR** does not involve any preprocessing, it is excluded from this measurement.

Online Processing Time. We measure the online processing time for a query averaged over multiple runs (explained in Sec 8.2) to evaluate the speedup.

Size of Pregenerated Information. We compare the sizes of the preprocessed information. **DCTAR** is again excluded. The size of the tree structure in **H-Mine** and the size of the *TAR Archive* in **TARA** are thus compared.

8.1 Evaluation of Preprocessing Time

We first compare the preprocessing times for **H-Mine**, **PARAS** and **TARA**. In the offline step, as the window slides, **H-Mine** (1) precomputes the frequent item sets and (2) stores them along with their associated *support* value into a tree structure. Whereas **TARA** (1) precomputes the frequent item sets, (2) derives the ruleset, (3) archives them along with the associated *support* and *confidence* values and (4) updates the *EPS-Index*. **PARAS** proceeds with the same process as **TARA** except that it does not utilize the archive nor does it keep the pregenerated information from the previous windows. Therefore, the total preprocessing time of **PARAS** is similar to **TARA** except for the archival time.

Fig. 10 compares the preprocessing time of **H-Mine** and **TARA** for all windows for the *retail*, *T5kL50N100*, *T2kL100N1k* datasets, with the system threshold settings summarized in Tab. 3. As shown, frequent item set generation occupies a relatively large portion of the preprocessing time as compared to other tasks. This confirms prior works [7] that rule generation is more efficient compared to frequent itemset generation. Overall, the additional preprocessing tasks in **TARA** require no more than 20% extra time than **H-Mine**. This extra time gives significant advantage to **TARA** in terms of truly interactive online performance and support of many advanced exploration operations.

8.2 Evaluation of Online Processing Time

Next, we compare the online processing times (y-axis in log scale) for our proposed operations. The user-specified parameters, namely *minsupp*, *minconf* and *time periods*, are varied. The examined queries fall into two categories: (1) Rule trajectory and parameter recommendation queries and (2) Ruleset comparison queries. In the first experiment, we test the performance of **TARA** against the three competitors using several query types, namely *Q1* and *Q3* in *single match* mode. Second, we use *Q2* in *exact match* mode to test the performance of **TARA** against others. We choose *Q1*, *Q2* and *Q3* because they cover the major exploration operations and subroutines in the online processing phase.

8.2.1 Trajectory and Parameter Recommendation

To process *Q1*, the system needs to find the rules that satisfy *minsupp* and *conf* in a single *time period* and examine their parameter values in other specified time periods. For **DCTAR**, it mines the rules from the transactions that fall into the last window and examines their parameter values by processing the transactions that fall into the 3 previous windows. For **PARAS**, the process is identical except that the rules are retrieved from the **PARAS** index built based upon the newest window. For **H-Mine**, the rules are derived and examined by using its item set index.

Impact of Varying Support and Confidence. To determine the effect of *minsupp*, we conduct several experiments by fixing *minconf* to a constant value and varying the *minsupp* value. Fig. 8 illustrate the query processing times for *retail*, *T5kL50N100*, *T2kL100N1k* and *webdocs* datasets with fixed *minconf* 0.4, 0.2, 0.2 and 0.4, respectively.

We observe that, **TARA** consistently outperforms **DCTAR** and **PARAS** by 6,7,7 and 5 orders and **H-Mine** by 3, 4, 4 and 4 orders of magnitude for *retail*, *T5kL50N100*, *T2kL100N1k* and *webdocs* datasets respectively. **TARA-S** stands for the implementation of **TARA** with the rule index inside each *time sensitive stable region* to support content based exploration (*Q5*). The merging of indexes when *dominated regions* are being collected incurs extra costs as compared to the **TARA** system without these rule indexes. Especially when the number of rules in the result is small, this extra cost results in similar or slower response time compared to **H-Mine** as shown in Figs. 8(b) and (c). The reason of the fast response of **TARA** is that it prepares sufficient amount of information in the offline stage, so that answering such queries is simply about searching the **TARA** index.

TARA-R shows the response time of returning the *time-sensitive stable region* which answers *Q3*. Since **PARAS** always builds the index for the latest window, in this particular experiment, it achieves the same response time as

Figure 8: Rule Trajectory and Parameter Recommendation: Varying Support

Figure 9: Rule Trajectory and Parameter Recommendation: Varying Confidence

Figure 10: Preprocessing Time

TARA because only regions that fall into the latest window are considered. All other systems are not capable of answering $Q3$. That is, using DCTAR and H-Mine, an analyst would need to generate all possible rules in the specified time period and then investigate all to find the answer.

Impact of Varying Confidence. Next, we fix the $minsupp$ to a constant value and vary the $minconf$ value. Fig. 9 illustrates the query processing times for *retail*, *T5kL50N100*, *T2kL100N1k* and *webdocs* datasets with fixed $minsupp$ 0.0002, 0.0012, 0.0012 and 0.1123, respectively. Overall, both **TARA** and **TARA-S** consistently perform several orders of magnitude better than the three competitors.

8.2.2 Ruleset Comparison Queries

$Q2$ returns the differences of the rulesets w.r.t two parameter settings that share the same time specification. In this particular experiment, the query is configured with the *exact match* mode. It returns the differences of two parameter setting across 4 windows. Since the DCTAR and H-Mine do not support such query, we implement a subroutine in their rule derivation module to determine if the parameter value of the rule satisfies one setting but not the other. This subroutine is optimized so that it does not generate the overlapping ruleset w.r.t 2 different settings. In this experiment, we either fix $minsupp$ or $minconf$ and vary the other one.

Impact of Varying 2nd Support. Fig. 11 illustrates the query processing times for *retail*, *T5kL50N100*, *T2kL100N1k* and *webdocs* datasets. The fixed min parameters for these datasets are $(minsupp_1, minconf_1, minsupp_2)$: (0.0002, 0.4, 0.4), (0.0012, 0.2, 0.2), (0.0012, 0.2, 0.2) and (0.1123, 0.4, 0.4), respectively. The query processing times increase

with an increase in the $minsupp$ because the increase of the deviation from $minsupp_1$ to $minsupp_2$ results in larger differences between the two parameter settings. In particular, **TARA** outperforms DCTAR and PARAS by 6,7,6 and 6 orders, H-Mine by 4, 5, 4 and 4 orders for *retail*, *T5kL50N100*, *T2kL100N1k* and *webdocs* datasets, respectively.

Impact of Varying 2nd Confidence. Fig. 12 illustrates the query processing times for *retail*, *T5kL50N100*, *T2kL100N1k* and *webdocs* datasets. The fixed min parameters for these four datasets are $(minsupp_1, minconf_1, minsupp_2)$: (0.0002, 0.4, 0.0002), (0.0012, 0.2, 0.0012), (0.0012, 0.2, 0.0012) and (0.1123, 0.4, 0.1123), respectively. **TARA** consistently performed several orders of magnitude better than the three competitors.

8.3 Evaluation of Archive Size

We compare the sizes of the pregenerated information in **TARA**, H-Mine and PARAS. For H-Mine, the size of the structure is determined by the number of frequent item sets times the number of processed partitions, while the size of pre-stored information in **TARA** is determined by the size of the *TAR Archive*. PARAS only pregenerates the association in a single window. Its maximum size is $3^n - 2^n + 1$ where n is the unique items in that particular window. The actual index sizes can be estimated by multiplying the number of instances with the average space required per instance.

Fig 13 shows the size of the H-Mine Index, *TAR Archive* and the actual number of uncompressed rule parameter values for our four datasets with the system threshold settings summarized in Tab. 3. As **TARA** pre-generates rules instead of only the item sets, the size of the *TAR Archive* is larger than the H-Mine index. However, our encoding technique achieves favorable compression as compared to uncompressed rule parameter values.

9. RELATED WORK

Temporal association mining. Adding the time dimension in the context of association rules was first mentioned in [14]. However, while more follow-on works [6, 9, 18] improve the efficiency of temporal association mining by maintaining intermediate frequent item sets, all of these approaches require the user to input a specific parameter setting. This one-at-a-time approach not only limits efficiency,

Figure 11: Ruleset Comparison: Varying 2nd Support

Figure 12: Ruleset Comparison: Varying 2nd Confidence

Figure 13: Size of the TAR Archive

but also provides very limited feedback for the user.

Interestingness of temporal associations. [12, 17] identify the importance of analyzing the interestingness measures of associations. In the context of time-variant data, [11] measures the changes of the interestingness of the association w.r.t its histories. It is suggested that the interest in the rule itself is primarily determined by the interestingness of its change over time. Neither of these works tackle interactive mining through precomputation. In contrast, we explore the space of interestingness parameters for prestoring data mining results to facilitate fast online mining.

Interactive association mining. Prior works [4, 5, 10] have explored the space of parameters for handling data mining requests. However this work is restricted to static data. These approaches do not consider the time dimension as a property of the pattern. Instead we now study the problem of incorporating the time dimension into the association mining exploration process.

10. CONCLUSION

We present the first framework for interactive temporal association analytics. Our **TARA** framework employs a novel evolving parameter space model for pre-generating rules such that near real-time performance is guaranteed for online mining. In a variety of tested cases, **TARA** outperforms the three state-of-the-art competitor techniques, each by several orders of magnitude, while offering a holistic exploration experience supporting new classes of time-variant rule analytics.

ABSTRACT

Record linkage, the process of identifying similar records that correspond to the same real-world entities across databases, is a well-established research problem in the database, data mining, and information retrieval communities. Computing distances between string values of records is the key component in order to determine the similarity of the represented entities. Due to the typically large volumes of records, a two-step process is followed. A blocking mechanism is first applied for grouping similar records together, and then a matching mechanism is performed for comparing the records which have been inserted into the same block. However, there does not exist any efficient blocking/matching mechanism which provides theoretical guarantees for identifying similar records which consist of strings. Towards this end, we put forth the novel notion of embedding string-based records into a Hamming space, where such a mechanism exists. The size of these embeddings is kept as small as needed in order to guarantee the correspondence of distances in that space to the types of errors that exist between strings, e.g., a missing or a modified character. We build embeddings whose size is 120 bits for representing accurately four fields of a publicly available data set. We also present a distance threshold-aware blocking technique for higher accuracy rates compared to blocking approaches which ignore the specified threshold. Our empirical study conducted on real-world data sets shows the efficacy achieved by our embedding method as compared to several existing solutions.

1. INTRODUCTION

The integration of data from disparate sources is increasingly being required as an important step towards the identification of similar entities across different sources. Known as entity resolution, record linkage, and data matching, the process of integrating data is an important problem in many data mining and knowledge engineering applications [10]. A wide range of real-world applications, including health-care,

government services, crime and fraud detection, national security, and businesses, require entity resolution techniques in order to enrich data quality and empower accurate decision making [2].

Since unique entity identifiers, which would allow a simple join between records, are often not available in databases, a common practice is to use personal identifying attributes, such as names and addresses. Due to the quadratic complexity of the number of comparisons required and the commonly large volumes of records, a two-step process is followed [29]. In the first step, a blocking mechanism is applied, which reduces the comparison space efficiently by creating blocks with potentially similar records. Then, in the second step, only the records within the same block are compared with each other. Moreover, the values of these attributes, which are well correlated with the entities being linked, often contain variations, errors, and misspellings which require the use of approximate matching solutions [2].

A widely adopted criterion that is used to determine the similarity between the string values of these attributes is their edit distance [20], which is the minimum number of character edit operations required to transform one string value into the other. Unfortunately, thus far there does not exist an efficient blocking/matching mechanism that works directly on records, which contain string values, and simultaneously provides theoretical guarantees for identifying all similar record pairs using the edit distance as the metric for determining their similarity. Furthermore, computing the edit distances for a large number of record pairs imposes a considerable non-negligible overhead. This can be tolerated for the traditional context of an off-line process but is not suitable for many emerging recent applications that require nearly real-time analysis, especially if they involve streaming data [5, 33].

For these reasons, a common practice is to embed string values into a metric space where such an efficient blocking/matching solution exists. For example, Hamming [17] and Jaccard [18] Locality-Sensitive Hashing (LSH) based blocking/matching mechanisms work in a Hamming and in a Jaccard space, respectively. Representing a string as a small-sized binary sequence in a Hamming space results in a particularly lightweight structure. Moreover, Hamming distance, which is the number of bits in which two binary sequences differ, can be computed very fast. These two features render those embeddings a perfect fit for distributed and real-time settings. One such example of a real-world application is a health surveillance system that continuously integrates data from hospitals and pharmacy stores by performing a large

number of distance computations in real-time.

Also, during the matching step, it is common practice to follow a decision model by applying to each record pair a rule, which classifies a pair of records as a matching or as a non-matching pair according to some distance thresholds specified for each attribute. Setting such a threshold arbitrarily or on an empirical basis may either impose additional unnecessary running time or generate incomplete results. LSH-based blocking mechanisms [17, 18] consider each record as an entity ignoring completely such classification rules during the blocking step. This record-level approach falls short in the presence of such rules, especially when different thresholds are specified for each attribute.

In this paper, we propose an embedding method of strings into a compact binary Hamming space where both the embeddings are of small size and the distances in that space correspond to certain types of errors, e.g., an accidentally deleted character, between strings. Therefore, one can specify accurately the threshold(s) required by the used blocking/matching mechanism in the embedding space. Furthermore, we adapt the blocking mechanism to the used classification rule and report the formal guarantees provided for identifying any similar pair by using the newly adapted mechanism. To the best of our knowledge, such an attribute-level LSH-based blocking/matching technique has not been proposed in the literature before.

The contributions of this paper are:

- An efficient embedding method of strings into a compact Hamming space resulting in lightweight, in terms of size, embeddings.
- A guaranteed correspondence of distances in the embedding space to certain types of errors between strings.
- An attribute-level LSH-based blocking scheme, which adapts to the used classification rule.
- An experimental evaluation of the proposed method compared with existing embedding solutions and using real-world data sets.

In the next section, we review the relevant literature, and in Section 3 we formulate the problem and motivate its importance. We outline the building components of our proposed method in Section 4, and in Section 5 we describe this method in detail. We empirically evaluate and compare our approach with existing embedding solutions in Section 6, and we conclude this paper with future research directions in Section 7.

2. RELATED WORK

A long line of research has been conducted in record linkage and various methods for computing similarities between records in an approximate manner have been proposed. We refer the interested reader to some recent surveys [2, 10]. Many techniques have been developed for the blocking and matching step aimed at reducing the comparison space and identifying as many similar record pairs as possible [3, 10].

For the blocking step, several approaches [6, 8, 12, 34] have been developed with the aim of being scalable to large data sets without sacrificing quality. Nevertheless, there are two methods which had great impact on the research community. The first is the sorted neighborhood method [12],

including all its variants, which first sorts all records from the participating data sets and then uses a fixed-sized sliding window over the sorted records in order to compare the pairs which are formulated within that window. The second is the canopy clustering technique [6] that relies on the idea of using a computationally cheap clustering approach to create high-dimensional overlapping clusters, from which blocks of candidate record pairs can then be generated. These methods though do not provide any guarantees for identifying record pairs that are similar nor scale well to large volumes of records.

Recently, randomized blocking/matching techniques, which mainly rely on Locality-Sensitive Hashing (LSH) [1], have received much attention [9, 15, 17, 18]. These techniques work in some metric space into which string values are embedded preserving their initial distances as accurately as possible. The most appealing property of these distance-based randomized techniques is that they provide theoretical guarantees for identifying each similar record pair in the embedding space with high probability.

For the matching step, a large body of work has also been conducted on similarity joins [35, 36, 11, 21, 24, 25, 30, 31, 32] where efficient and scalable approximate joins are facilitated by using several metrics during the matching step such as the edit, Jaccard, and cosine metrics [2]. Especially, the authors in [35, 21, 25, 30, 31] have devised efficient techniques for finding similar string values using the edit distance metric, however they focus on individual such values, whereas our work proposes a solution for finding similar records, which usually consist of multiple strings. All the above-mentioned metrics though use strings or high-dimensional vectors of integers, which are not suitable structures for highly demanding environments either in terms of communication or of computational cost. Three other state-of-the-art embedding methods, introduced in [14, 18, 27], are used as our competitors and are presented in detail in Section 6.

3. PROBLEM DEFINITION

Let us assume that two data custodians, who own databases A and B , respectively, engage themselves into a process for identifying the common entities among their records. They are allowed to make use of the services offered by an independent party, whom we call Charlie. The two data custodians agree to use a common set of n_f attributes, each denoted by f_i where $i = 1, \dots, n_f$, based on which they can exchange and compare their records. We denote by $u_{\mathcal{E}}^{(f_i)}$ the distances between the values of attribute f_i , and by $\vartheta_{\mathcal{E}}^{(f_i)}$ the specified threshold for this attribute. They also need to provide an additional attribute, let us call it Id , for the role of an identifier of each record. The data custodians submit their records to Charlie whose duty is to identify any pairs of *similar* records that belong to different data sets.

DEFINITION 1 (A SIMILAR RECORD PAIR). A record pair $r_A \in A$ and $r_B \in B$ is considered as similar if for each attribute f_i , it holds that $u_{\mathcal{E}}^{(f_i)} \leq \vartheta_{\mathcal{E}}^{(f_i)}$ in the metric space $(\mathcal{E}, d_{\mathcal{E}})$, where \mathcal{E} is the original space in which the string values of all records of A and B exist, and $d_{\mathcal{E}}$ is the edit distance used as the metric on \mathcal{E} .

Due to the generally large size of the data sets at hand, Charlie will use a randomized blocking/matching mecha-

Algorithm 1 Mapping a q -gram to a position of a q -gram vector.

Input: a q -gram gr .
Output: The index ind in the q -gram vector.
1: $ind = 0$
2: **for** $i = 1, \dots, q$ **do**
3: $ch = gr[i]$ // Extract each character ch from gr .
4: $ind = ind + ord(ch) \times |S|^{q-i}$ // Function $ord(\cdot)$ returns the order (zero-based) of character ch in S .
5: **end for**

nism, which both handles efficiently large volumes of data, and provides theoretical guarantees of performance in approximate matching by identifying each similar record pair with a specified (high) probability. However, such known mechanisms work in different metric spaces than \mathcal{E} . For this reason, Charlie embeds the string values into a Hamming metric space $(\mathcal{H}, d_{\mathcal{H}})$, where such a mechanism already exists. Additionally, there should exist a guaranteed correspondence between distances in \mathcal{H} and the type of errors in \mathcal{E} by keeping the size of the embeddings in \mathcal{H} as small as possible. Given this correspondence, the thresholds required can be easily specified in \mathcal{H} , which will result in identifying each pair of records regarded as similar in \mathcal{E} .

DEFINITION 2 (AN EFFICIENT EMBEDDING METHOD). *Given an efficient blocking/matching mechanism in \mathcal{H} , construct an embedding method of strings from \mathcal{E} into \mathcal{H} , where errors in \mathcal{E} are identifiable in \mathcal{H} separately for each attribute f_i using embeddings whose sizes are as small as possible depending on the lengths of the strings in f_i .*

4. BACKGROUND

In this section, we outline the building blocks utilized by our proposed scheme.

4.1 q -gram Vectors

A q -gram vector is a deterministic structure for representing a string value in the Hamming space. Such structures have been used in [18] and [19] for representing distinct attribute values and whole records, respectively. Each position of a q -gram vector represents a distinct q -gram which is a group of q consecutive characters in a string value. By assuming that the alphabet S of q -grams is the set of the upper-case letters, the size of a q -gram vector is $m = |S|^q = 26^q$ positions. Let us denote a bijection $F : \{gr_1, gr_2, \dots, gr_m\} \rightarrow \{0, \dots, m-1\}$, which maps each q -gram for a certain alphabet S to an integer, termed also as the index ind of that q -gram. The logic behind F is illustrated in Algorithm 1. Therefore, by this mapping, we obtain a set of indexes, denoted by U_s , that indicates which positions of the respective q -gram vector will be set to 1. Figure 1 illustrates how a string is represented by a bigram¹ vector. A record-level q -gram vector is built by concatenating the corresponding attribute-level q -gram vectors and its size is $\bar{m} = n_f \times m$. The space in which these record-level q -gram vectors exist is $\mathcal{H} = \{0, 1\}^{\bar{m}}$.

4.2 Hamming LSH-based Blocking/Matching

Due to the large number of records that occur in many of today's databases, the randomized Hamming Locality-Sensitive Hashing (LSH) technique [1], denoted by HB, is

¹Bigrams are the q -grams with $q = 2$.

Figure 1: Representing the string ‘JOHN’ as a bigram vector denoted by BV .

Table 1: Interpretation of the most used variables throughout this paper.

T_l	An independent blocking group where $l = 1, \dots, L$ used by the HB.
h_l	A composite hash function used to specify the bucket of some T_l into which a c -vector, defined in Section 5.2, is stored.
K	The number of base hash functions used by a h_l .
U_s	The set of indexes of the respective q -grams of a string s .
$d_{\mathcal{S}}$	The metric applied on space \mathcal{S} where $\mathcal{S} \in \{\mathcal{H}, \widehat{\mathcal{H}}, \mathcal{E}, \mathcal{T}\}$.
$u_{\mathcal{S}}$	Distance measured by using metric $d_{\mathcal{S}}$.
$\vartheta_{\mathcal{S}}$	The specified distance threshold in space \mathcal{S} .
\bar{m}_{opt}	The optimal size of a record-level c -vector.
n_f	The number of common attributes which participate in the linkage process.
f_i	An attribute where $i = 1, \dots, n_f$. When used as a superscript in parentheses, it denotes the attribute-level value, e.g., $u_{\mathcal{H}}^{(f_i)}$, $K^{(f_i)}$, $h_l^{(f_i)}$ etc.
$b^{(f_i)}$	The average number of q -grams of the values of the corresponding attribute f_i .

used as the blocking/matching technique in order to identify each similar pair of record-level q -gram vectors, which exist in \mathcal{H} , with high probability. Mechanism HB utilizes L independent hash tables, termed also as blocking groups. Each hash table, denoted by T_l where $l = 1, \dots, L$, consists of key-bucket pairs where a bucket hosts a linked list which is aimed at grouping similar q -gram vectors. Moreover, each hash table has been assigned a composite hash function h_l which consists of a fixed number K of base hash functions. A base hash function applied to a q -gram vector returns the value of its j -th position where $j \in \{0, \dots, \bar{m} - 1\}$ chosen uniformly at random.

DEFINITION 3 (A HAMMING LSH FAMILY). *A family ϕ of composite hash functions has the following key property for any pair of record-level q -gram vectors denoted by $QV_1, QV_2 \in \mathcal{H}$ whose Hamming distance is $u_{\mathcal{H}}$ [1]:*

$$\text{If } u_{\mathcal{H}} \leq \vartheta_{\mathcal{H}} \text{ then } \Pr[h_l(QV_1) = h_l(QV_2)] \geq p^K, \quad (1)$$

where p denotes the success probability of a base hash function and is equal to $p = 1 - \frac{\vartheta_{\mathcal{H}}}{\bar{m}}$.

Intuitively, the smaller the Hamming distance is, the higher the probability for a h_l to produce the same result. The result of a h_l , which constitutes the blocking key, applied to

Figure 2: Hashing a record-level bigram vector BV , with $Id='A1'$, by h_1 and h_2 . For illustration purposes, we set $K = 4$ and $L = 2$.

a q -gram vector specifies into which bucket, termed also as block, this q -gram vector will be stored². Figure 2 illustrates how a record-level bigram vector is hashed.

During the matching step, we scan the buckets of each T_i and formulate pairs of q -gram vectors, which belong to different data sets. By using this redundant blocking scheme, we amplify the probability of identifying similar q -gram vectors, but we also increase both the utilized space and the running time in order to store the generated T_i 's. We therefore determine the optimal number of the T_i 's that should be utilized by setting [1]:

$$L = \lceil \frac{\ln(\delta)}{\ln(1 - p^K)} \rceil. \quad (2)$$

Each similar q -gram vector pair will be returned with high probability $1 - \delta$, as δ is usually set to a small value, say $\delta = 0.1$. The value for K can be set empirically since the correctness of the scheme is guaranteed by setting L appropriately. In [16], a method for choosing the optimal value for K is presented, where the authors by sampling record pairs and by experimenting with several values for K , choose the value that minimizes the estimated running time. The value of K can be set empirically since the completeness, with respect to the identification of the matching pairs, of the mechanism is guaranteed by Equation (2), by deriving the optimal value for L . The value of K should be sufficiently large because otherwise the blocking keys will not reflect the variations of the bit sequences of the q -gram vectors. The direct side-effect of this deficiency will be the generation of a small number of buckets in each T_i , which will be overpopulated by mostly dissimilar pairs.

Not surprisingly though, q -gram vectors render inefficient and cumbersome the HB mainly due to their sparsity as will be explained in Section 5.2. In that section, towards mitigating this sparsity and reducing their size, we propose an alternative embedding scheme of the string values into \mathcal{H} in order to leverage the efficiency of HB.

5. AN EFFICIENT EMBEDDING METHOD

In this section, we instantiate our method, termed as cBV-HB, which relies on embedding string values by using their respective q -grams into a compact Hamming space. The reason for choosing this space is twofold. Firstly, we argue that by corresponding types of errors in \mathcal{E} to distances in \mathcal{H} , one can easily specify the distance threshold(s) required by HB. Secondly, the HB mechanism is a fast and accurate method as experimentally demonstrated in [17], and it is

²More precisely, we store only the corresponding Id 's.

Figure 3: The indexes in bold indicate the differing bigrams between s_1 and s_2 , which result in distances being equal to 4 and 3 in \mathcal{H} for the substitute and delete (insert) operations, respectively ($m = 676$).

works in Hamming spaces. We next (a) illustrate the correspondence between distances in \mathcal{H} and types of errors in \mathcal{E} by using the q -gram vectors, (b) propose an embedding method which can be used by HB for efficient identification of similar record pairs, and (c) present an attribute-level LSH-based blocking technique which brings the importance of the classification rule into the blocking step.

5.1 Corresponding Types of Errors in \mathcal{E} to Distances in \mathcal{H}

An error between a pair of string values is formally quantified by edit distance. In the literature, several variants of edit distance exist using different perturbation operations, as the errors are termed in the edit distance context³. We consider the basic perturbation operations (substitute, insert, and delete) defined for the Levenshtein distance [20] and correspond these basic operations to distances in \mathcal{H} by using the q -gram vectors. We present an illustrative running example where the initial error-free string value is $s_1='JONES'$, unless otherwise stated and we set $q = 2$ (bigrams). The perturbed values are stored in variable s_2 . In this example, we use two bigram vectors, denoted by BV_1 and BV_2 for representing s_1 and s_2 , respectively.

Substitute perturbation operation: This type of perturbation operation changes a single character in s_1 and materializes the main reason for errors and misspellings commonly found in string values. Assume the value $s_2='JONAS'$,

³We use the terms *perturbation operation* and *error* interchangeably. Usually, a perturbation operation occurs intentionally and an error unintentionally.

the distance $u_{\mathcal{H}}$ between BV_1 and BV_2 is 4, as shown in Figure 3, due to the 4 differing bigrams, which are ‘NE’ and ‘ES’ in s_1 and ‘NA’ and ‘AS’ in s_2 ⁴. Distance may be smaller in case a differing bigram overlaps with a common bigram. For instance, by perturbing $s_1 = \text{‘SHANNEN’}$ as $s_2 = \text{‘SHENNEN’}$, we produce two differing bigrams in s_1 , which are ‘HA’ and ‘AN’, and two more in s_2 namely ‘HE’ and ‘EN’. The latter though overlaps with a common bigram found in both s_1 and s_2 . Therefore, only bigrams ‘HA’, ‘AN’, and ‘HE’ affect $u_{\mathcal{H}}$ which in this case is 3. We conclude that for this type of perturbation operation $u_{\mathcal{H}} \leq 4 \times u_{\mathcal{E}}$.

Delete and insert perturbation operations: Another common error that emerges when typing string values is the omission of a character. This causes the generation of a smaller number of bigrams for s_2 . As an illustration, by setting $s_2 = \text{‘JONS’}$, we get two differing bigrams in s_1 , which are ‘NE’ and ‘ES’ and only 1 in s_2 , which is ‘NS’ (see Figure 3). Hence, for the delete operation, it holds that $u_{\mathcal{H}} \leq 3 \times u_{\mathcal{E}}$. Likewise, the insert is quite similar to the delete operation ($s_2 = \text{‘JONEAS’}$) since it is essentially as a delete operation in s_1 .

The above-mentioned observations, which hold for any q -gram vector pair with $q \geq 2$, lead to the definition of an upper bound for a distance $u_{\mathcal{E}}$ which corresponds to a $u_{\mathcal{H}}$ scaled by a constant factor α :

$$u_{\mathcal{H}} \leq \alpha \times u_{\mathcal{E}}. \quad (3)$$

The factor α depends on the type of the applied perturbation operation, as explained before, and determines the deviation between distances from \mathcal{E} to \mathcal{H} , commonly termed as *distortion* [13].

In the Jaccard space \mathcal{J} , which consists of the sets U_s where s stands for each possible string value, by using the Jaccard metric [2] the distance between $s_1 = \text{‘JONES’}$ and $s_2 = \text{‘JONAS’}$ is $u_{\mathcal{J}} = 1 - |U_{s_1} \cap U_{s_2}| / |U_{s_1} \cup U_{s_2}| \simeq 0.667$. Comparing though $s_1 = \text{‘WASHINGTON’}$ with $s_2 = \text{‘WASHANGTON’}$, the distance is affected by the length of the strings resulting in $u_{\mathcal{J}} \simeq 0.364$. In contrast, the Hamming distance is constantly $u_{\mathcal{H}} = 4$ in both cases. Hence using the Jaccard metric, one should take into account the length of strings in order to set the threshold appropriately. This task is not easy or sometimes is not feasible at all.

5.2 Embedding Strings into a Compact Space

In this subsection, we propose an embedding method, which preserves the distances from \mathcal{E} , into a compact space that consists of small-sized embeddings. These embeddings can be particularly useful in highly demanding distributed environments, which deal with large volumes of records, for efficient communication. Our method adapts the size of the q -gram vectors to the expected number of characters that a record holds as needed. For example, the average number of bigrams for the *LastName* attribute of the NCVR database [4], which is a large publicly available data set that we will use in our experiments in Section 6, is only 5.0 bigrams. Therefore, the generated attribute-level bigram vectors would be quite sparse due to the few bigrams produced by each string value. This sparsity though has negative effects during the application of the HB. The h_l ’s by

⁴We pad the first and the last character, e.g., ‘_JONES_’ in order to include all the characters in 2 bigrams.

Figure 4: Representing the string ‘JOHN’ as a c -vector denoted by cBV .

sampling randomly bit positions from such q -gram vectors mostly choose 0’s, which has as a side-effect the formulation of a small number of overpopulated buckets. Thus, the HB boils down to an inefficient *all-pairs* comparison process. Moreover, by assuming n_f attributes, the size of a record-level q -gram vector would be quite large, namely $\mathcal{O}(n_f \times m)$ bits. On account of these drawbacks, we embed the string values of each attribute into a new space $\hat{\mathcal{H}}$ which also uses the Hamming metric. This space consists of compact q -gram vectors, termed as c -vectors, which are of size $m^{(f_i)} \ll |S|^q$, that will be exactly specified later, for each attribute f_i . We introduce the dependency of the size of c -vectors on the average number $b^{(f_i)}$ of q -grams of the values of the corresponding attribute f_i . This dependency will allow us to be as efficient as possible by adjusting the sizes accordingly and simultaneously preserving the distances from \mathcal{H} . Towards this end, we hash the indexes in U_s of a string value s by randomly chosen, pairwise independent hash functions of the form $g(x) = [(ax+b) \bmod P] \bmod m$, where $x \in U_s$, P is a large prime number (e.g., $2^{31}-1$) and a, b are randomly chosen integers from $(0, P)$.

Figure 4 shows the creation of a c -vector by hashing the bigrams of a string. However, during the hash operations of the elements of U_s , a number of collisions may occur if two elements of U_s hash to the same index in the c -vector. This happens because the number of all possible q -grams is much larger than $m^{(f_i)}$. A collision is formally defined as $g(x) = g(y)$ for any $x, y \in U_s$ with $x \neq y$ and the probability $\Pr[g(x) = g(y)]$ is $\frac{1}{m^{(f_i)}}$. By considering the guarantees quoted in the previous section, the collisions, in which differing q -grams of a pair of c -vectors participate, affect the distances in $\hat{\mathcal{H}}$. These collisions result in misleadingly classifying non-matching as matching pairs.

As an illustration, let us assume the c -vectors with $q = 2$, generated by the values $s_1 = \text{‘JONES’}$ and $s_2 = \text{‘JONAS’}$ of an attribute f_i . We expect the distance to be $u_{\mathcal{H}}^{(f_i)} = u_{\hat{\mathcal{H}}}^{(f_i)} = 4$ due to the differing bigrams generated by the suffices ‘NES’ and ‘NAS’. However, if during the hash operations of s_2 , the results corresponding to the bigrams ‘NA’ and ‘AS’ collide, then the $u_{\hat{\mathcal{H}}}^{(f_i)}$ will be 1 bit less than the $u_{\mathcal{H}}^{(f_i)}$. Therefore, the value for $m^{(f_i)}$ should be adequately specified so that both the HB can be efficiently applied and the distances should be preserved.

The phenomenon of collisions is described in the Birthday Paradox Problem [23] on which the following lemma relies. In the calculations below, we drop superscript (f_i) for better readability.

LEMMA 1. The expected number of collisions $E[c]$ by hashing b q -grams for attribute f_i to a c -vector with size m is:

$$E[c] = b - E[v], \quad (4)$$

where $E[v]$ denotes the expected number of positions which both hold 1 and no collisions have occurred.

PROOF. The indexes of positions of a c -vector, representing a string s of an attribute f_i , are uniformly chosen by $g(\cdot)$, therefore the probability of choosing any position for each $x \in U_s$ is $\frac{1}{m}$. Let the indicator variable I_j denote for the position with index j , where $j \in \{0, \dots, m-1\}$, the content in that position. The probability that a certain position with index j is not chosen ($I_j = 0$) after hashing b q -grams is:

$$\Pr[I_j = 0] = (1 - \frac{1}{m})^b. \quad (5)$$

Thus, the probability that the position with index j is finally chosen is $\Pr[I_j = 1] = 1 - \Pr[I_j = 0]$. The expected number v of positions holding 1 is:

$$E[v] = \sum_{j=0}^{m-1} E[I_j] = mE[I_j] = m(1 - (1 - \frac{1}{m})^b). \quad (6)$$

Then, by subtracting $E[v]$ from b , we arrive at the desired result. \square

Let us denote by ρ the maximum number of collisions we can tolerate during the generation of the c -vectors. Then, using ρ and the above lemma, we state the following theorem:

THEOREM 1. By expecting b q -grams in the corresponding strings, the optimal size of the c -vectors for some attribute f_i is:

$$m_{opt} = \lceil \frac{b - \rho}{1 - e^{-r}} \rceil, \quad (7)$$

where $E[c] \leq \rho$ with confidence $1 - r$.

PROOF. We first specify the value of ρ and expand Equation (4) by using Equation (6) as follows:

$$\begin{aligned} E[c] &= b - m(1 - (1 - \frac{1}{m})^b) \leq \rho \Rightarrow \\ m(1 - (1 - \frac{1}{m})^b) &\geq b - \rho. \end{aligned} \quad (8)$$

By using the fact that $-(1 - \frac{1}{m})^b \geq -e^{-\frac{b}{m}}$, we derive an upper bound for the left hand side of the second inequality in (8) which is written as:

$$m(1 - e^{-\frac{b}{m}}) \geq b - \rho. \quad (9)$$

We then substitute $\frac{b}{m}$ with a constant r , where $r < 1$ since it always holds that $b < m$. This constant denotes the ratio between the number of q -grams to the size m . Intuitively, smaller values for r increase our confidence, quantified as $1 - r$, that collisions will not occur at the cost of a larger size m . Finally, we solve for m in (9), and derive the optimal size, as illustrated in Equation (7), where we keep only the equal sign, since we want to be as optimal as possible. \square

In Section 6, we show experimentally that by setting $r < 1/3$, we just increase m_{opt} without earning a lot in terms of accuracy.

Algorithm 2 Matching the c -vector pairs formulated in the buckets of the T_i 's.

Input: $cBV_B \in B$
1: $C \leftarrow \text{new UniqueCollection}()$
2: $\quad \quad \quad // C$ is a collection of unique Id 's.
3: **for** $l = 1, \dots, L$ **do**
4: $\quad Id_list \leftarrow T_l.get(h_l(cBV_B))$
5: $\quad \quad \quad // \text{Object } Id_list \text{ is a linked list of } Id\text{'s.}$
6: **for** $i = 1, \dots, Id_list.size()$ **do**
7: $\quad \quad Id \leftarrow Id_list[i]$
8: **if** ($\text{not } C.contains(Id)$) **then**
9: $\quad \quad cBV_A \leftarrow \text{retrieve}(Id)$
10: $\quad \quad \text{rule}(cBV_A, cBV_B)$
11: $\quad \quad \quad // \text{A classification rule applied for each } c\text{-vector pair.}$
12: $\quad \quad C.add(Id)$
13: **end if**
14: **end for**
15: **end for**

Table 2: Primitive operations used by Algorithm 2.

$get(x)$	Return the linked list, to which the specified key x is mapped.
$size()$	Return the size of a linked list.
$contains(x)$	Return <i>true</i> if the unique collection contains element x .
$retrieve(x)$	Retrieve a c -vector with $Id = x$ from the data store.
$add(x)$	Add value x to a unique collection.

For example, by assuming $b^{(f_1)} = 5.1$ and $b^{(f_3)} = 20.0$ from Table 3, by setting in (7) $\rho = 1$ and $r = 1/3$, we derive values $m_{opt}^{(f_1)} = 15$ and $m_{opt}^{(f_3)} = 68$, respectively. We use the ceiling function $\lceil \cdot \rceil$ to $m_{opt}^{(f_i)}$ because the size of a c -vector should be an integer.

For each attribute, Charlie transforms the strings he receives from Alice and Bob into c -vectors using the optimal size $m_{opt}^{(f_i)}$ by sampling randomly and uniformly strings from the data sets and computing $b^{(f_i)}$. By concatenating the attribute-level c -vectors, Charlie then builds the record-level structures, whose size \overline{m}_{opt} is compact and adapted to the needs of each attribute.

5.3 Outline of the Blocking/Matching Step

Let us denote by cBV_A and cBV_B the record-level c -vectors which belong to data sets A and B , respectively. We first hash each cBV_A and store its Id in the buckets of the T_i 's. Then, we hash each cBV_B to the T_i 's in order to formulate c -vector pairs for performing the distance computations. Due to the *redundant* blocking model that we follow, certain pairs of c -vectors might be formulated in several T_i 's. On account of this redundancy, we incorporate a de-duplicating mechanism in HB in order to prevent the repetitive distance computations of duplicate pairs as can be seen in Algorithm 2. For each bucket that cBV_B maps to, we retrieve the Id 's already stored therein (line 4), and query them against a collection of unique elements⁵ (line 8). If an Id is not found in that collection, then the corresponding distance computation is performed otherwise it is dropped. Table 2 quotes a description of each primitive operation used by Algorithm 2. We have to note that our method is capable of handling an arbitrary number of data

⁵This collection is instantiated by a *HashSet* object in Java programming language.

sets (two or more) belonging to different data custodians.

5.4 Attribute-level LSH-based Blocking

Mechanism HB assumes record-level c -vectors where by sampling randomly and uniformly their bits builds the T_l 's. During the matching step, a decision model is applied in order to classify the formulated record pairs as matching or as non-matching. In its simplest form, a decision model might be a classification rule, which applies a logical condition to the values of each attribute by comparing them to an attribute-level threshold. Therefore, there is no guarantee that c -vector pairs are formulated according to the classification rule during the blocking step. For instance, by using the attributes in Table 3, a classification rule might be $(u^{f_1} \leq 4) \wedge (u^{f_2} \leq 8)^6$. This rule is more strict to errors in the values of the first attribute while being more tolerant to errors in the values of the second attribute. HB though is unaware of that rule, and uses the underlying values of attributes on an equal basis. In this subsection, we propose a method for adjusting the HB mechanism to the classification rule. This adjustment has as a result the formulation of c -vector pairs which are much closer in terms of distance to the logic of the classification rule.

To begin with, the hash functions during the blocking step should use each attribute separately rather than sampling bits uniformly from the record-level c -vectors. To this end, we choose a value for each attribute-level $K^{(f_i)}$, in the same sense as we have described in Section 4.2. A $K^{(f_i)}$ specifies the number of base hash functions for each $h_l^{(f_i)}$ which work on the attribute-level c -vectors corresponding to attribute f_i . By assuming (a) n_c attributes, where $n_c \leq n_f$, that participate in each rule, (b) independence among the string values of each attribute, and (c) the attribute-level success probability of a base hash function is $p^{(f_i)} = 1 - \frac{\vartheta^{(f_i)}}{m_{opt}^{(f_i)}}$, we state the following definitions for any pair of record-level c -vectors that exhibit distances $u^{(f_i)} \leq \vartheta^{(f_i)}$ as follow:

DEFINITION 4 (AND OPERATOR). *By using the AND operator (\wedge) on certain attributes in the classification rule, the probability of a record-level c -vector pair to collide into the same bucket of a T_l is:*

$$p_{\wedge} \geq \prod_{i=1}^{n_c} (p^{(f_i)})^{K^{(f_i)}}. \quad (10)$$

Using the AND operator, the structure of the blocking groups used, described in Section 4.2, is maintained. The blocking keys for each f_i are concatenated resulting in a compound blocking key that is finally inserted into some T_l .

DEFINITION 5 (OR OPERATOR). *By using the OR operator (\vee) on certain attributes in the classification rule, the probability of a record-level c -vector pair to collide into the same bucket of any $T_l^{(f_i)}$ is:*

$$p_{\vee} \geq (p^{(f_1)})^{K^{(f_1)}} + (p^{(f_2)})^{K^{(f_2)}} - (p^{(f_1)})^{K^{(f_1)}} \times (p^{(f_2)})^{K^{(f_2)}}. \quad (11)$$

Without loss of generality, in Equation (11), we show only the case where $n_c = 2$ attributes. For a larger number n_c of attributes, the inclusion-exclusion principle [22] should be used.

⁶We drop the space subscript from distances and thresholds, since from now on we focus on $\hat{\mathcal{H}}$.

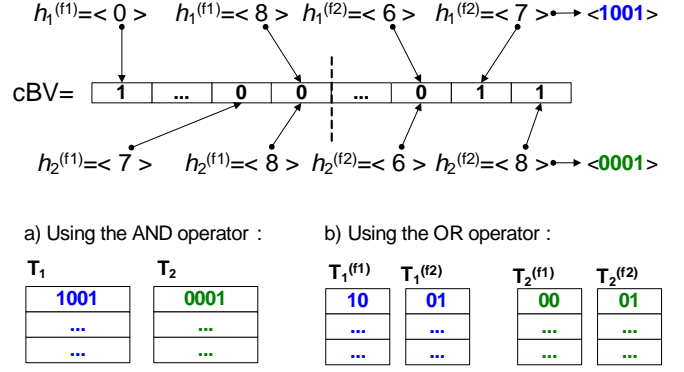

Figure 5: Applying attribute-level hashing to a c -vector cBV which consists of 2 attribute-level c -vectors. For illustration purposes, we set $K = 4$ ($K^{(f_i)} = 2$) and $L = 2$.

When using the OR operator, the structure of the blocking groups changes considerably. For each attribute f_i , which is part of the OR rule, for each blocking group, we build an independent hash table, denoted by $T_l^{(f_i)}$, that stores the blocking keys of this specific attribute. Therefore, given n_c attributes in the OR rule, we end up with $L \times n_c$ hash tables. Intuitively, one would classify a c -vector pair as a matching one, if this pair is formulated in at least one $T_l^{(f_i)}$, regardless of the remaining outcomes.

DEFINITION 6 (NOT OPERATOR). *By using the NOT operator (\neg) on a certain attribute, the probability of any pair of record-level c -vectors not to collide into the same bucket of a $T_l^{(f_i)}$ is:*

$$p_{\neg} \geq 1 - (p^{(f_i)})^{K^{(f_i)}}. \quad (12)$$

The NOT operator assumes one attribute f_i and thus one hash table for each blocking group. One would assume the true value as outcome, if a certain pair has not been formulated in the corresponding $T_l^{(f_i)}$'s.

These revised probability bounds adjust the number L of the blocking groups⁷ used by substituting p^K in Equation (2). The new value of L is larger using an AND rule, and smaller using an OR rule than the standard record-level LSH-based blocking approach. Using these operators, we build the basic classification rules which are depicted in Figure 5. The blocking group of the NOT operator does not include any modifications because we just change what we consider as a true outcome.

In addition, by using these basic rules and their corresponding blocking groups, we may compose compound classification rules which consist of several *subrules*. Such compound rules might be:

- $C_1 = [(u^{(f_1)} \leq \vartheta^{(f_1)}) \wedge (u^{(f_2)} \leq \vartheta^{(f_2)})] \vee [(u^{(f_3)} \leq \vartheta^{(f_3)}) \wedge (u^{(f_4)} \leq \vartheta^{(f_4)})]$ where two separate blocking structures for the AND subrules should be built. The first blocking structure comprises the blocking groups of attributes f_1 , and f_2 , while the second one contains the attributes f_3 , and f_4 . During the blocking mechanism, the blocking keys will be built from the

⁷The value of L may vary among the blocking structures used.

corresponding attribute-level c -vectors and will be inserted into the corresponding T_i 's. Since an OR operator joins the two subrules, a pair will be returned if it will be formulated in the blocking structure of either subrule. Thus, during the matching phase, for each c -vector from data set B , we formulate all possible pairs in all the corresponding buckets. Then, a pair is considered as a matching one, if it is formulated in either blocking structure.

- $C_2 = [(u^{(f_1)} \leq \vartheta^{(f_1)}) \vee [(u^{(f_2)} \leq \vartheta^{(f_2)})] \wedge [(u^{(f_3)} \leq \vartheta^{(f_3)}) \vee (u^{(f_4)} \leq \vartheta^{(f_4)})]$ where four separate blocking structures for the OR operators should be built. The main difference between C_1 and C_2 is that using C_2 , a pair should be formulated in both blocking structures of the subrules in order to be considered as a matching pair.
- $C_3 = (u^{(f_1)} \leq \vartheta^{(f_1)}) \wedge [\neg(u^{(f_2)} \leq \vartheta^{(f_2)})]$. Using C_3 , a pair is returned if it is formulated in the blocking structure for f_1 , but not found in the blocking structure for f_2 .

The space needed for building the blocking groups of a rule using an AND operator is $\mathcal{O}(L)$, while using an OR operator is $\mathcal{O}(n_c \times L)$.

6. EVALUATION

In this section, we describe the experimental settings, the baseline methods, the data sets used, as well as the achieved results. We conducted experiments using two publicly available real-world databases which are (a) the NCVR database [4] and (b) the DBLP bibliography database⁸. By using both these data sets, which exhibit different properties such as the average lengths of string values, we obtain several insights through the experimental results. The attributes used are listed in Table 3.

We developed a software prototype which by using as input the above-mentioned databases, extracts records and creates two data sets, denoted by A and B , respectively, where one can specify the perturbation frequency, number of perturbation operations, and number of perturbed records in B for each chosen record in A . We apply (a) a light perturbation scheme, termed as PL , where we perturb the values of one randomly chosen attribute, and (b) a heavy scheme, termed as PH , where we apply one perturbation to the values of the first two attributes and two perturbations to the values of the third attribute. We denote the thresholds for each perturbation scheme as $\vartheta_{PL}^{(f_i)}$ and $\vartheta_{PH}^{(f_i)}$ regardless of the used space. The number of records in A (and B) is 1,000,000, while the probability of choosing a record from A in order to apply a perturbation scheme and then place it in B , is set to 0.5. The experiments were executed on a dual-core Pentium PC with 32 GB of main memory. The software components are developed using the Java programming language (JDK 1.7) and are available from the authors.

Quality measures. The Pairs Completeness (PC), Pairs Quality (PQ), and Reduction Ratio (RR) measures [3] are employed to evaluate the quality of both our method and the baseline methods which are discussed in detail below. The set of truly matching record pairs is denoted by M

Table 3: Attribute-level parameters used for each type of data set by using bigrams.

	attribute	$b^{(f_i)}$	$m_{opt}^{(f_i)}$	$K^{(f_i)}$
NCVR	$f_1=FirstName$	5.1	15	5
	$f_2=LastName$	5.0	15	5
	$f_3=Address$	20.0	68	10
	$f_4=Town$	7.2	22	
	$\overline{m}_{opt} = 120$			
DBLP	$f_1=FirstName$	4.8	14	5
	$f_2=LastName$	6.2	19	5
	$f_3=Title$	64.8	226	12
	$f_4=Year$	3.0	8	
	$\overline{m}_{opt} = 267$			

and the set of identified matching pairs by \mathcal{M} . The accuracy in finding the matching record pairs is indicated by the PC measure, which is equal to $PC = |\mathcal{M} \cap M|/|M|$. The PQ measure shows the efficiency in generating mostly matching pairs with respect to candidate pairs, namely $PQ = |\mathcal{M} \cap M|/|CR|$, where CR is the set of candidate pairs. The RR metric indicates the percentage in the reduction of the comparison space $A \times B$, which is equal to $RR = 1.0 - |CR|/|A \times B|$. We ran each experiment 50 times and plotted the average values of these measures in the figures shown below.

6.1 Baseline Methods

We compare our approach $cBV-HB$ with three state-of-the-art embedding approaches for record linkage. The first is the h-CC algorithm of **HARRA** [18], where two de-duplicated data sets are linked. In this approach, all attribute values of a record are represented by a single bigram vector. However, setting the same position of a bigram vector by identical bigrams, which belong to different attributes, may lead to ambiguous evaluation of distances and consequently to reduced accuracy. **HARRA** employs the Min-Hash LSH-based blocking/matching mechanism which uses the Jaccard metric, as described in Section 5.1, for performing the distance computations. Since **HARRA** selects arbitrary values for K and L , by experimenting for better results, we set $L = 30$ and $L = 90$ ($K = 5$) for each perturbation scheme, respectively. We performed several distance computations using the vector space that **HARRA** works, where one cannot focus on separate attributes, using perturbed string values and ended up choosing $\vartheta_{PL} = 0.35$ and $\vartheta_{PH} = 0.45$ ⁹ as a nice balance between accuracy and efficiency. During the blocking phase, we hash those vectors by applying random permutations of their indexes and we choose the index of the minimum non-zero element of these permutations as the result of each base hash function. However, we mostly end up with an index holding 0, which implies that more elements of each permutation should be used until we find an index that is set to 1. As a result, similar records are inserted into different buckets. The blocking and matching mechanisms are conducted iteratively and separately for each T_i . When two records are classified as a matching pair, they are subsequently excluded from the remaining iterations.

⁹All thresholds are set after experimenting exhaustively using the initial and corresponding perturbed values.

⁸<http://dblp.uni-trier.de/xml/>

Another method we compare our approach with is *BfH* presented in [17], which uses the HB, as described in Section 4.2, on Bloom filters. A Bloom filter is a data structure used to represent the elements of a set in order to support membership queries efficiently in terms of time and space required. It has been shown in [27] that by embedding string values into Bloom filters, distances from the original space are preserved. More specifically, a Bloom filter is a bitmap array initialized with zeros and created by hashing the bigrams of a string value by using independent composite cryptographic hash functions such as MD5 and SHA1 [26]. Field-level Bloom filters are created using a size of 500 bits by using 15 cryptographic hash functions for each bigram, as proposed in [27]. We set $K = 30$ and $\delta = 0.1$ while thresholds are set as $\vartheta_{PL}^{(f_1)} = 45$ ($L = 4$), $\vartheta_{PH}^{(f_1)} = \vartheta_{PH}^{(f_2)} = 45$, and $\vartheta_{PH}^{(f_3)} = 90$ ($L = 43$). We have to note that these attribute-level thresholds are used only during the matching step. A key observation for the Bloom filter space, which is a high-dimensional binary Hamming space, is that distances are affected by the number of bigrams. For example, using the field-level Bloom filters, described before, the Hamming distance between ‘JOHN’ and ‘JAHN’ is 54. In contrast, the Hamming distance between ‘SCALABILITY’ and ‘SCELABILITY’ is equal to 37. This variation in distance, although in both cases there exists a single error in the initial string values, causes difficulties in specifying effectively the distance threshold.

Finally, we compare *cBV-HB* with the *StringMap* algorithm [14] which is used to embed string values into a Euclidean space. Initially for each attribute, *StringMap* iterates the strings of both data sets in order to form d orthogonal directions (axes). Each such direction is specified by two strings, termed as pivots, whose distances are as far from each other as possible. Yet, the process of specifying the pivot values is quite expensive since it includes several iterations of the data sets. Then, for each string, we compute its coordinates on these d axes, which results in a vector of values of dimensionality d . As the authors suggest [14], dimensionality d is set to 20 for each attribute and thresholds $\vartheta_{PL}^{(f_1)} = 4.5$, $\vartheta_{PH}^{(f_1)} = \vartheta_{PH}^{(f_2)} = 4.5$, and $\vartheta_{PH}^{(f_3)} = 7.7$, for each scheme respectively. We utilize the Euclidean LSH-based blocking/matching mechanism [17], specifically developed for finding similar points in Euclidean spaces. As in *BfH*, the above-mentioned thresholds are used only during the matching step. The value of K is set to 5 which generates $L = 29$ and $L = 194$ blocking groups [7] for each perturbation scheme, respectively. We call this method *SM-EB* due to the combination of *StringMap* and the blocking/matching mechanism used.

6.2 Experimental Results

Accuracy. In the first series of experiments, for the rules:

- $C_1 = (u^{(f_1)} \leq \vartheta^{(f_1)}) \wedge (u^{(f_2)} \leq \vartheta^{(f_2)}) \wedge (u^{(f_3)} \leq \vartheta^{(f_3)})$,
- $C_2 = [(u^{(f_1)} \leq \vartheta^{(f_1)}) \wedge (u^{(f_2)} \leq \vartheta^{(f_2)})] \vee (u^{(f_3)} \leq \vartheta^{(f_3)})$,
and
- $C_3 = (u^{(f_1)} \leq \vartheta^{(f_1)}) \wedge \neg(u^{(f_2)} \leq \vartheta^{(f_2)})$,

we measured the *PC* and *PQ* rates of our attribute-level blocking and compare them with the rates of the standard LSH-based approach, which, as described in Section 4.2, during the blocking phase samples bits uniformly from the

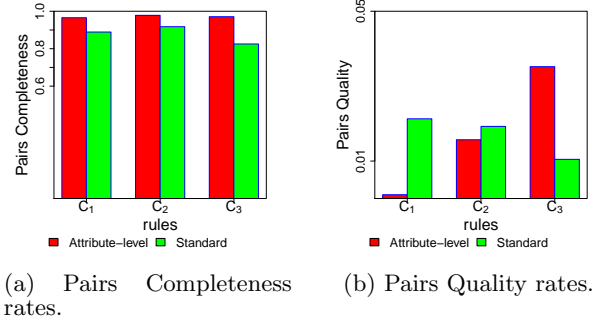

Figure 6: Attribute-level Pairs Completeness and Pairs Quality evaluation using the NCVR-based data sets.

Figure 7: Evaluation of accuracy by setting several values to confidence r , from Equation (7), and measuring the *PC* rates using the NCVR-based data sets ($K = 35$).

whole record-level *c*-vector. Clearly, Figure 6(a) shows that by using this rule-aware blocking phase, the *PC* rates are constantly higher than those using the standard LSH-based blocking approach. Nevertheless, the largest difference lies in C_3 where the standard approach is unable to articulate the NOT operator, comparing and discarding rather late any such non-matching pairs. Conversely, those pairs, in the rule-aware blocking phase, are not formulated at all and are never brought for comparison. The *PQ* rates, illustrated in Figure 6(b), for C_1 are lower than the standard approach due to the larger number of blocking groups required. For C_2 , the utilization of two hash tables in a blocking group, because of the OR operator, drops initially the *PQ* rates which balance later, during the matching phase, due to the better quality of the formulated pairs. We then experimented by setting several values to confidence r , for less collisions from Equation (7), and measured the corresponding *PC* rates. Since we want to be as optimal as possible, the choice of $r = 1/3$ exhibits both high *PC* rates and the sizes of the *c*-vectors are kept to a desired level. As can be seen in Figure 7, we do not gain a lot in terms of accuracy by setting $r < 1/3$.

Running time. By choosing several values for K we measure the elapsed running time. Specifically, for both perturbation schemes we vary K between 20 and 40, which results in generating different values for L^{10} (blocking groups). Figure 8(a) clearly illustrates that there is a near-optimal value of K , which is 30 for both perturbation schemes, that minimizes the running time. This is quite reasonable because by increasing K we adjust the *selectivity* of our block-

¹⁰As shown in Section 4.2, L depends on K , δ , $\vartheta_{\hat{H}}$, and \bar{m}_{opt} .

(a) Applying *cBV-HB* by using several values for K . (b) Time needed for converting the data sets into the respective embeddings of each method.

Figure 8: Running time evaluation using the NCVR-based data sets.

ing mechanism, i.e., buckets are populated with Id 's corresponding mostly to similar c -vectors. The consequence of higher selectivity is a decrease in running time due to the smaller number of the formulated c -vector pairs. Nevertheless, there is a value for K ($K = 35$) where the time needed for building the blocking groups dominates the total running time which starts to increase.

Comparison with the baseline methods. For the next set of experiments, we first measured the average number $b^{(f_i)}$ of bigrams of string values for each attribute listed in Table 3. We underline the difference in the values of $b^{(f_i)}$ between the two sources of data sets and evaluate its impact on the experimental results which follow below. For scheme *PL*, since there is a single perturbation operation, we set $K = 30$, $\delta = 0.1$, and $\vartheta_{PL}^{(f_i)} = 4$, which generate $L = 6$, and $L = 3$ blocking groups, without applying attribute-level blocking, for each source of data sets used. For scheme *PH*, we apply attribute-level blocking by using the rule C_1 , as defined previously, and the parameters in Table 3. We set the thresholds as $\vartheta_{PH}^{(f_1)} = \vartheta_{PH}^{(f_2)} = 4$, and $\vartheta_{PH}^{(f_3)} = 8$, which yield $L = 178$ and $L = 62$ blocking groups, respectively.

In Figure 8(b), we evaluate the time needed in order to embed the data sets into the space required by each method. The bigram vectors used by *HARRA* require the least amount of time because a single vector is used for the bigrams generated of the whole record with the side-effects in accuracy, which will be discussed below. The vectors utilized by *SM-EB* exhibit a large amount of time due to the distance computations performed for specifying the pivots.

Figures 9(a) and 9(b) show that the *PC* rates of our method are constantly above 95% by using both sources of data sets. These figures also indicate that *cBV-HB* is the only method which exhibits stable *PC* rates regardless of the source of data sets used. Furthermore, by applying *PH* in the presence of a certain classification rule our method adjusts to it during the blocking step by generating the required number of blocking groups separately for each attribute as the rule defines. However, this attribute-level adjustment requires a larger number of blocking groups, which results in reduced *PQ* rates due to the larger number of the formulated pairs (Figures 10(a) and 10(b)).

The *PC* rates of *SM-EB* are rather low, as Figure 9(a) suggests, especially when using *PH*. This happens due to the insufficient distance-preserving property of the used embedding method. This insufficiency has also another drawback, which is the population of blocks with truly non-matching

(a) Using the NCVR-based data sets. (b) Using the DBLP-based data sets.

Figure 9: Pairs Completeness (accuracy) evaluation.

(a) Using the NCVR-based data sets. (b) Using the DBLP-based data sets.

Figure 10: Pairs Quality evaluation.

pairs. These pairs, although being similar in the Euclidean space, exhibit large distances in the original space, which results in low *PQ* rates, as can be clearly seen in Figures 10(a) and 10(b).

In *HARRA*, the early removal of records in each iteration may lead to missed matching pairs as well, since those records do not participate in the subsequent iterations. Initially, the *PC* rates of *HARRA* were below 0.77. We had to increase considerably the number of blocking groups¹¹ in order to achieve better rates, which were approximately equal to 0.82 as shown in Figure 9(a). However, the side-effect of increasing the number of blocking groups was the low *PQ* rates as illustrated in Figures 10(a) and 10(b). Especially by using the DBLP-based data sets, the larger number of bigrams combined with the utilization of a single bigram vector for all attributes in a record increased considerably the probability of comparing bigram vectors with identical bigrams belonging to different attributes. This disambiguation, as expected, deteriorated the *PC* rates which fell below 0.75 (Figure 9(b)).

The Bloom filters, which are used by *BfH*, seem to preserve the initial distances from the original space, as confirmed by the high *PC* rates. However, the accuracy guarantees, provided by the HB, refer to the Bloom filter space and there is no study in the literature that corresponds distances from that space to distances in \mathcal{E} with a specified distortion. The authors in [17] provide only some empirical observations with respect to this correspondence without any rigorous justifications. The dependency of distances, in the Bloom filter space, on the length of the initial string

¹¹We actually doubled the number of blocking groups in order to give more chances to similar records to be grouped together.

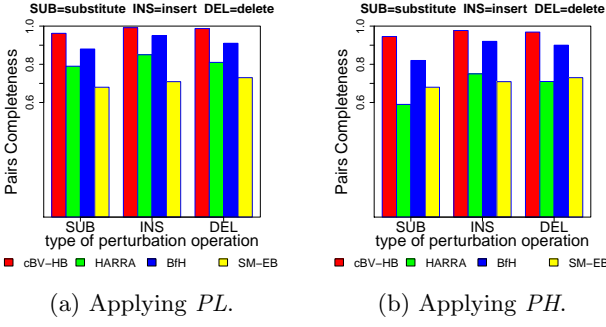

Figure 11: Evaluating Pairs Completeness by focusing on each type of perturbation operation by using the NCVR-based data sets.

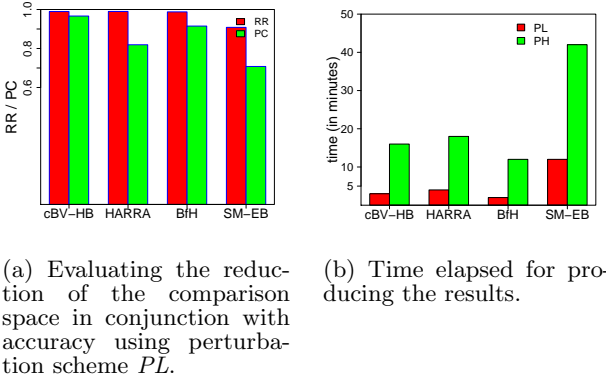

Figure 12: Evaluating the efficiency of each method by using the NCVR-based data sets.

values, as demonstrated previously, explains the increased accuracy by using the DBLP-based data sets (Figure 9(b)). On the contrary, distances in $\hat{\mathcal{H}}$ depend only on the type of error and by no means on the length of the initial string values. The PQ rates of *BfH* are slightly higher than *cBV-HB* mainly due to the larger number of the cryptographic hash functions used for creating the Bloom filters, which results in a larger number of positions set to 1. These bit patterns hashed by the h_i 's produce a larger number of buckets in each T_i , which host a smaller number of pairs than *cBV-HB*.

Another factor that does not affect the PC rates of our method is the type of the applied perturbation operation as demonstrated in Figures 11(a) and 11(b) by applying PL and PH , respectively. Our method attains excellent performance and the PC rate barely falls below 0.95 only when applying the substitute operations. In general, we observe that all methods exhibit a lower PC rate for pairs which have been perturbed by the substitute operation, which indicates a higher distortion in all spaces. For PH , only *BfH* exhibits comparable performance, as can be seen in Figure 11(b). However, the two operations performed in the values of the *Address* attribute resulted in missing some pairs especially when both were substitute operations.

Figure 12(a) illustrates together the RR and the PC rates so that one can easily evaluate the efficiency of each method. RR is high for all the compared methods except for *SM-EB*

EB where the formulated blocks are overwhelmed by non-matching pairs. The reduction of the comparison space though keeps up with high accuracy only for *cBV-HB* and *BfH*, where our method performs better than *BfH* in terms of accuracy by at least 5%. Overall, this provides additional validation of the robustness and practicality of our method. These high RR rates affect the running time positively which is below 5 minutes for PL for both methods, as depicted in Figure 12(b). By applying PH though, the running time increases due to the larger number of blocking groups generated for this perturbation scheme. In *HARRA*, the early pruning of records in each iteration reduces the running time but the results are far from accurate. As expected, *SM-EB* exhibits the highest running time by a large margin among all the compared methods due to the large number of the formulated vector pairs.

7. CONCLUSIONS AND FUTURE EXTENSIONS

In this paper we have proposed a method to embed strings into a compact binary Hamming space in order to apply HB which is an efficient blocking/matching mechanism. The embeddings are of small size, e.g., a record of four strings is represented by 120 bits, and simultaneously the initial distances are preserved as the supporting set of experiments confirmed. Furthermore, we have adapted the LSH-based blocking mechanism to the used classification rule for highly accurate results. We have considered and provided formal guarantees for rules using the AND, OR, and NOT operators. In addition, we have also demonstrated the use of compound classification rules, which include several sub-rules. For the future, we aim to investigate a distance-preserving and lightweight embedding method for the Jaro-Winkler metric, which was specifically developed for measuring distances between attributes that denote personal information such as names, surnames, or addresses. We also aim to extend the experimental part by comparing the effectiveness of our method with the baselines in identifying records with missing or non-standardized values. The initial results indicate that by applying PH , the gain in accuracy compared to the baselines is larger. Another interesting research avenue could be the adaptation of our method to the privacy-preserving context by applying two-party techniques [28]. The compact data structures used for representing the records could be an ideal fit in the protocols introduced in [17, 19] which are used for comparing those records in a secure manner.

ABSTRACT

Entity Resolution constitutes a quadratic task that typically scales to large entity collections through blocking. The resulting blocks can be restructured by Meta-blocking in order to significantly increase precision at a limited cost in recall. Yet, its processing can be time-consuming, while its precision remains poor for configurations with high recall. In this work, we propose new meta-blocking methods that improve precision by up to an order of magnitude at a negligible cost to recall. We also introduce two efficiency techniques that, when combined, reduce the overhead time of Meta-blocking by more than an order of magnitude. We evaluate our approaches through an extensive experimental study over 6 real-world, heterogeneous datasets. The outcomes indicate that our new algorithms outperform all meta-blocking techniques as well as the state-of-the-art methods for block processing in all respects.

1. INTRODUCTION

A common task in the context of Web Data is *Entity Resolution* (ER), i.e., the identification of different entity profiles that pertain to the same real-world object. ER suffers from low efficiency, due to its inherently quadratic complexity: every entity profile has to be compared with all others. This problem is accentuated by the continuously increasing volume of heterogeneous Web Data; *LOD-Stats*¹ recorded around 1 billion triples for Linked Open Data in December, 2011, which had grown to 85 billion by September, 2015. Typically, ER scales to these volumes of data through *blocking* [4].

The goal of blocking is to boost precision and time efficiency at a controllable cost in recall [4, 5, 21]. To this end, it groups similar profiles into clusters (called *blocks*) so that it suffices to compare the profiles within each block [7, 8]. Blocking methods for Web Data are confronted with high levels of noise, not only in attribute values, but also in attribute names. In fact, they involve an unprecedented schema heterogeneity: Google Base² alone encompasses 100,000 distinct schemata that correspond to 10,000 entity types [17]. Most blocking methods deal with these high levels of

¹<http://stats.lod2.eu>

²<http://www.google.com/base>

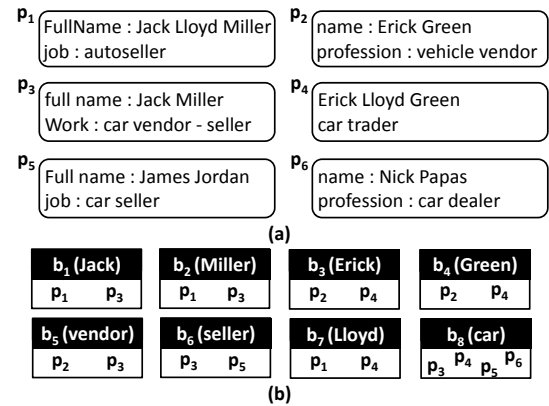

Figure 1: (a) A set of entity profiles, and (b) the corresponding blocks produced by Token Blocking.

schema heterogeneity through a schema-agnostic functionality that completely disregards schema information and semantics [5]. They also rely on *redundancy*, placing every entity profile into multiple blocks so as to reduce the likelihood of missed matches [4, 22].

The simplest method of this type is Token Blocking [21]. In essence, it splits the attribute values of every entity profile into tokens based on whitespace; then, it creates a separate block for every token that appears in at least two profiles. To illustrate its functionality, consider the entity profiles in Figure 1(a), where p_1 and p_2 match with p_3 and p_4 , respectively; Token Blocking clusters them in the blocks of Figure 1(b). Despite the schema heterogeneity and the noisy values, both pairs of duplicates co-occur in at least one block. Yet, the total cost is 13 comparisons, which is rather high, given that the brute-force approach executes 15 comparisons.

This is a general trait of redundancy-based blocking methods: in their effort to achieve high recall in the context of noisy and heterogeneous data, they produce a large number of unnecessary comparisons. These come in two forms [22, 23]: the *redundant* ones repeatedly compare the same entity profiles across different blocks, while the *superfluous* ones compare non-matching profiles. In our example, b_2 and b_4 contain one redundant comparison each, which are repeated in b_1 and b_3 , respectively; all other blocks entail superfluous comparisons between non-matching entity profiles, except for the redundant comparison p_3 - p_5 in b_8 (it is repeated in b_6). In total, the blocks of Figure 1(b) involve 3 redundant and 8 superfluous out of the 13 comparisons.

Block Processing. To improve the quality of redundancy-based blocks, methods such as Meta-blocking [5, 7, 22], Comparison Propagation [21] and Iterative Blocking [27] aim to process them in the optimal way (see Section 2 for more details). Among these methods, Meta-blocking achieves the best balance between preci-

Figure 2: (a) A blocking graph extracted from the blocks in Figure 1(b), (b) one of the possible edge-centric pruned blocking graphs, and (c) the new blocks derived from it.

sion and recall [22, 23], and is the focus of this work.

Meta-blocking restructures a block collection B into a new one B' that contains a significantly lower number of unnecessary comparisons, while detecting almost the same number of duplicates. It operates in two steps [7, 22, 23]: first, it transforms B into the blocking graph G_B , which contains a vertex v_i for every entity profile p_i in B , and an edge $e_{i,j}$ for every pair of co-occurring profiles p_i and p_j (i.e., entity profiles sharing at least one block). Figure 2(a) depicts the graph for the blocks in Figure 1(b). As no parallel edges are constructed, every pair of entities is compared at most once, thus eliminating all *redundant* comparisons.

Second, it annotates every edge with a weight analogous to the likelihood that the incident entities are matching. For instance, the edges in Figure 2(a) are weighted with the Jaccard similarity of the lists of blocks associated with their incident entity profiles. The lower the weight of an edge, the more likely it is to connect non-matching entities. Therefore, Meta-blocking discards most *superfluous* comparisons by pruning the edges with low weights. A possible approach is to discard all edges with a weight lower than the overall mean weight ($1/4$). This yields the pruned graph in Figure 2(b). The restructured block collection B' is formed by creating a new block for every retained edge – as depicted in Figure 2(c). Note that B' maintains the original recall, while reducing the comparisons from 13 to just 5.

Open issues. Despite the significant enhancements in efficiency, Meta-blocking suffers from two drawbacks:

(i) There is plenty of room for raising its precision, especially for the configurations that are more robust to recall. The reason is that they retain a considerable portion of redundant and superfluous comparisons. This is illustrated in our example, where the restructured blocks of Figure 2(c) contain 3 superfluous comparisons in b'_3 , b'_4 and b'_5 .

(ii) The processing of voluminous datasets involves a significant overhead. The corresponding blocking graphs comprise millions of nodes that are strongly connected with billions of edges. Inevitably, the pruning of such graphs is very time-consuming; for example, a graph with 3.3 million nodes and 35.8 billion edges requires 16 hours, on average, on commodity hardware (see Section 6.3).

Proposed Solution. In this paper, we describe novel techniques for overcoming both weaknesses identified above.

First, we speed up Meta-blocking in two ways:

(i) We introduce *Block Filtering*, which intelligently removes profiles from blocks, in which their presence is unnecessary. This acts as a pre-processing technique that shrinks the blocking graph, discarding more than half of its unnecessary edges, on average. As a result, the running time is also reduced to half, on average.

(ii) We accelerate the creation and the pruning of the blocking graph by minimizing the computational cost for edge weighting, which is the bottleneck of Meta-blocking. Our approach reduces its running time by 30% to 70%.

In combination, these two techniques restrict drastically the overhead of Meta-blocking even on commodity hardware. For example, the blocking graph mentioned earlier is now processed within just 3 hours, instead of 16.

Second, we enhance the precision of Meta-blocking in two ways:

(i) We redefine two pruning algorithms so that they produce restructured blocks with no redundant comparisons. On average, they save 30% more comparisons for the same recall.

(ii) We introduce two new pruning algorithms that rely on a generic property of the blocking graph: the reciprocal links. That is, our algorithms retain only the edges that are important for both incident profiles. Their recall is slightly lower than the existing techniques, but precision raises by up to an order of magnitude.

We analytically examine the performance of our methods using 6 real-world established benchmarks, which range from few thousands to several million entities. Our experimental results designate that our algorithms consistently exhibit the best balance between recall, precision and run-time for the main types of ER applications among all meta-blocking techniques. They also outperform the best relevant methods in the literature to a significant extent.

Contributions & Paper Organization. In summary, we make the following contributions:

- We improve the running time of Meta-blocking by an order of magnitude in two complementary ways: by cleaning the blocking graph from most of its noisy edges, and by accelerating the estimation of edge weights.

- We present four new pruning algorithms that raise precision by 30% to 100% at a small (if any) cost in recall.

- We experimentally verify the superior performance of our new methods through an extensive study over 6 datasets with different characteristics. In this way, our experimental results provide insights into the best configuration for Meta-blocking, depending on the data and the application at hand. The code and the data of our experiments are publicly available for any interested researcher.³

The rest of the paper is structured as follows: Section 2 delves into the most relevant works in the literature, while Section 3 elaborates on the main notions of Meta-blocking. In Section 4, we introduce two methods for minimizing its running time, and in Section 5, we present new pruning algorithms that boost the precision of Meta-blocking at no or limited cost in recall. Section 6 presents our thorough experimental evaluation, while Section 7 concludes the paper along with directions for future work.

2. RELATED WORK

Entity Resolution has been the focus of numerous works that aim to tame its quadratic complexity and scale it to large volumes of data [4, 8]. Blocking is the most popular among the proposed approximate techniques [5, 7]. Some blocking methods produce disjoint blocks, such as Standard Blocking [9]. Their majority, though, yields overlapping blocks with redundant comparisons in an effort to achieve high recall in the context of noisy and heterogeneous data [4]. Depending on the interpretation of redundancy, blocking methods are distinguished into three categories [22]:

(i) The *redundancy-positive* methods ensure that the more blocks two entity profiles share, the more likely they are to be matching. In this category fall the Suffix Arrays [1], Q-grams Blocking [12], Attribute Clustering [21] and Token Blocking [21].

(ii) The *redundancy-negative* methods ensure that the most similar entity profiles share just one block. In Canopy Clustering [19], for instance, the entity profiles that are highly similar to the cur-

³See <http://sourceforge.net/projects/erframework> for both the code and the datasets.

rent seed are removed from the pool of candidate matches and are exclusively placed in its block.

(iii) The *redundancy-neutral* methods yield overlapping blocks, but the number of common blocks between two profiles is irrelevant to their likelihood of matching. As such, consider the single-pass Sorted Neighborhood [13]: all pairs of profiles co-occur in the same number of blocks, which is equal to the size of the sliding window.

Another line of research focuses on developing techniques that optimize the processing of an existing block collection, called *block processing methods*. In this category falls Meta-blocking [7], which operates exclusively on top of redundancy-positive blocking methods [20, 21]. Its pruning can be either unsupervised [22] or supervised [23]. The latter achieves higher accuracy than the former, due to the composite pruning rules that are learned by a classifier trained over a set of labelled edges. In practice, though, its utility is limited, as there is no effective and efficient way for extracting the required training set from the input blocks. For this reason, we exclusively consider unsupervised Meta-blocking in this work.

Other prominent block processing methods are the following:

(i) *Block Purging* [21] aims for discarding oversized blocks that are dominated by redundant and superfluous comparisons. It automatically sets an upper limit on the comparisons that can be contained in a valid block and purges those blocks that exceed it. Its functionality is coarser and, thus, less accurate than Meta-blocking, because it targets entire blocks instead of individual comparisons. However, it is complementary to Meta-blocking and is frequently used as a pre-processing step [22, 23].

(ii) *Comparison Propagation* [21] discards all redundant comparisons from a block collection without any impact on recall. In a small scale, this can be accomplished directly, using a central data structure H that hashes all executed comparisons; then, a comparison is executed only if it is not contained in H . Yet, in the scale of billions of comparisons, Comparison Propagation can only be accomplished indirectly: the input blocks are enumerated according to their processing order and the Entity Index is built. This is an inverted index that points from entity ids to block ids. Then, a comparison p_i-p_j in block b_k is executed (i.e., non-redundant) only if it satisfies the Least Common Block Index condition (LeCoBI for short). That is, if the id k of the current block b_k equals the least common block id of the profiles p_i and p_j . Comparison Propagation is competitive to Meta-blocking, but targets only redundant comparisons. We compare their performance in Section 6.4.

(ii) *Iterative Blocking* [27] propagates all identified duplicates to the subsequently processed blocks so as to save repeated comparisons and to detect more duplicates. Hence, it improves both precision and recall. It is competitive to Meta-blocking, too, but it targets exclusively redundant comparisons between matching profiles. We employ it as our second baseline method in Section 6.4.

3. PRELIMINARIES

Entity Resolution. An *entity profile*, p , is defined as a uniquely identified collection of name-value pairs that describe a real-world object. A set of profiles is called *entity collection*, E . Given E , the goal of ER is to identify all profiles that describe the same real-world object; two such profiles, p_i and p_j , are called *duplicates* ($p_i \equiv p_j$) and their comparison is called *matching*. The set of all duplicates in the input entity collection E is denoted by $D(E)$, with $|D(E)|$ symbolizing its size (i.e., the number of existing duplicates).

Depending on the input entity collection(s), we identify two ER tasks [4, 21, 22]: (i) *Dirty ER* takes as input a single entity collection with duplicates and produces as output a set of equivalence clusters. (ii) *Clean-Clean ER* receives two duplicate-free, but overlapping entity collections, E_1 and E_2 , and identifies the matching

entity profiles between them. In the context of Databases, the former task is called *Deduplication* and the latter *Record Linkage* [4].

Blocking improves the run-time of both ER tasks by grouping similar entity profiles into blocks so that comparisons are limited between co-occurring profiles. Placing an entity profile into a block is called *block assignment*. Two profiles, p_i and p_j , assigned to the same block are called *co-occurring* and their comparison is denoted by $c_{i,j}$. An individual block is symbolized by b , with $|b|$ denoting its *size* (i.e., number of profiles) and $\|b\|$ denoting its *cardinality* (i.e., number of comparisons). A set of blocks B is called *block collection*, with $|B|$ denoting its size (i.e., number of blocks) and $\|B\|$ its cardinality (i.e., total number of comparisons): $\|B\| = \sum_{b \in B} \|b\|$.

Performance Measures. To assess the effectiveness of a blocking method, we follow the best practice in the literature, which treats entity matching as an orthogonal task [4, 5, 7]. We assume that two duplicate profiles can be detected using any of the available matching methods as long as they co-occur in at least one block. $D(B)$ stands for the set of co-occurring duplicate profiles and $|D(B)|$ for its size (i.e., the number of detected duplicates).

In this context, the following measures are typically used for estimating the *effectiveness* of a block collection B that is extracted from the input entity collection E [4, 5, 22]:

(i) *Pairs Quality* (PQ) corresponds to precision, assessing the portion of comparisons that involve a *non-redundant* pair of duplicates. In other words, it considers as true positives the matching comparisons and as false positives the superfluous and the redundant ones (given that some of the redundant comparisons involve duplicate profiles, PQ offers a pessimistic estimation of precision). More formally, $PQ = |D(B)|/\|B\|$. PQ takes values in the interval $[0, 1]$, with higher values indicating higher precision for B .

(ii) *Pairs Completeness* (PC) corresponds to recall, assessing the portion of existing duplicates that can be detected in B . More formally, $PC = |D(B)|/|D(E)|$. PC is defined in the interval $[0, 1]$, with higher values indicating higher recall.

The goal of blocking is to maximize both PC and PQ so that the overall effectiveness of ER exclusively depends on the accuracy of the entity matching method. This requires that $|D(B)|$ is maximized, while $\|B\|$ is minimized. However, there is a clear trade-off between PC and PQ : the more comparisons are executed (higher $\|B\|$), the more duplicates are detected (higher $|D(B)|$), thus increasing PC ; given, though, that $\|B\|$ increases quadratically for a linear increase in $|D(B)|$ [10, 11], PQ is reduced. Hence, a blocking method is effective if it achieves a good balance between PC and PQ .

To assess the *time efficiency* of a block collection B , we use two measures [22, 23]:

(i) *Overhead Time* ($OTime$) measures the time required for extracting B either from the input entity collection E or from another block collection B' .

(ii) *Resolution Time* ($RTime$) is equal to $OTime$ plus the time required to apply an entity matching method to all comparisons in the restructured blocks. As such, we use the Jaccard similarity of all tokens in the values of two entity profiles for entity matching – this approach does not affect the relative efficiency of the examined methods and is merely used for demonstration purposes.

For both measures, the lower their value, the more efficient is the corresponding block collection.

Meta-blocking. The redundancy-positive block collections place every entity profile into multiple blocks, emphasizing recall at the cost of very low precision. Meta-blocking aims for improving this balance by restructuring a redundancy-positive block collection B into a new one B' that contains a small part of the original unnecessary comparisons, while retaining practically the same recall [22]. More formally, $PC(B') \approx PC(B)$ and $PQ(B') \gg PQ(B)$.

Weighting Schemes	Pruning Algorithms
1) Aggregate Reciprocal Comparisons (ARCS)	1) Cardinality Edge Pruning (CEP)
2) Common Blocks (CBS)	2) Cardinality Node Pruning (CNP)
3) Enhanced Common Blocks (ECBS)	3) Weighted Edge Pruning (WEP)
4) Jaccard Similarity (JS)	4) Weighted Node Pruning (WNP)
5) Enhanced Jaccard Similarity (EJS)	

Figure 3: All configurations for the two parameters of Meta-blocking: the weighting scheme and the pruning algorithm.

Aggregate Reciprocal Comparisons Scheme	$ARCS(p_i, p_j, B) = \sum_{b_k \in B_{ij}} \frac{1}{ b_k }$
Common Blocks Scheme	$CBS(p_i, p_j, B) = B_{ij} $
Enhanced Common Blocks Scheme	$ECBS(p_i, p_j, B) = CBS(p_i, p_j, B) \cdot \log \frac{ B }{ B_i } \cdot \log \frac{ B }{ B_j }$
Jaccard Scheme	$JS(p_i, p_j, B) = \frac{ B_{ij} }{ B_i + B_j - B_{ij} }$
Enhanced Jaccard Scheme	$EJS(p_i, p_j, B) = JS(p_i, p_j, B) \cdot \log \frac{ B }{ B_i } \cdot \log \frac{ B }{ B_j }$

Figure 4: The formal definition of the five weighting schemes. $B_i \subseteq B$ denotes the set of blocks containing p_i , $B_{i,j} \subseteq B$ the set of blocks shared by p_i and p_j , and $|v_i|$ the degree of node v_i .

Central to this procedure is the blocking graph G_B , which captures the co-occurrences of profiles within the blocks of B . Its nodes correspond to the profiles in B , while its undirected edges connect the co-occurring profiles. The number of edges in G_B is called *graph size* ($|E_B|$) and the number of nodes *graph order* ($|V_B|$).

Meta-blocking prunes the edges of the blocking graph in a way that leaves the matching profiles connected. Its functionality is configured by two parameters: (i) the scheme that assigns weights to the edges, and (ii) the pruning algorithm that discards the edges that are unlikely to connect duplicate profiles. The two parameters are independent in the sense that every configuration of the one is compatible with any configuration of the other (see Figure 3).

In more detail, five schemes have been proposed for weighting the edges of the blocking graph [22]. Their formal definitions are presented in Figure 4. They all normalize their weights to $[0, 1]$ so that the higher values correspond to edges that are more likely to connect matching profiles. The rationale behind each scheme is the following: ARCS captures the intuition that the smaller the blocks two profiles share, the more likely they are to be matching; CBS expresses the fundamental property of redundancy-positive block collections that two profiles are more likely to match, when they share many blocks; ECBS improves CBS by discounting the effect of the profiles that are placed in a large number of blocks; JS estimates the portion of blocks shared by two profiles; EJS improves JS by discounting the effect of profiles involved in too many non-redundant comparisons (i.e., they have a high node degree).

Based on these weighting schemes, Meta-blocking discards part of the edges of the blocking graph using an *edge-* or a *node-centric* pruning algorithm. The former iterates over the edges of the blocking graph and retains the globally best ones, as in Figure 2(b); the latter iterates over the nodes of the blocking graph and retains the locally best edges. An example of node-centric pruning appears in Figure 5(a); for each node in Figure 2(a), it has retained the incident edges that exceed the average weight of the neighborhood. For clarity, the retained edges are directed and outgoing, since they might be preserved in the neighborhoods of both incident profiles. Again, every retained edge forms a new block, yielding the restructured block collection in Figure 5(b).

Every pruning algorithm relies on a *pruning criterion*. Depending on its scope, this can be either a *global* criterion, which applies to the entire blocking graph, or a *local* one, which applies to an

Figure 5: (a) One of the possible node-centric pruned blocking graphs for the graph in Figure 2(a). (b) The new blocks derived from the pruned graph.

individual node neighborhood. With respect to its functionality, the pruning criterion can be a *weight threshold*, which specifies the minimum weight of the retained edges, or a *cardinality threshold*, which determines the maximum number of retained edges.

Every combination of a pruning algorithm with a pruning criterion is called *pruning scheme*. The following four pruning schemes were proposed in [22] and were experimentally verified to achieve a good balance between *PC* and *PQ*:

(i) *Cardinality Edge Pruning* (CEP) couples the edge-centric pruning with a global cardinality threshold, retaining the top- K edges of the entire blocking graph, where $K = \lfloor \sum_{b \in B} |b|/2 \rfloor$.

(ii) *Cardinality Node Pruning* (CNP) combines the node-centric pruning with a global cardinality threshold. For each node, it retains the top- k edges of its neighborhood, with $k = \lfloor \sum_{b \in B} |b|/|E| - 1 \rfloor$.

(iii) *Weighted Edge Pruning* (WEP) couples edge-centric pruning with a global weight threshold equal to the average edge weight of the entire blocking graph.

(iv) *Weighted Node Pruning* (WNP) combines the node-centric pruning with a local weight threshold equal to the average edge weight of every node neighborhood.

The *weight-based* schemes, WEP and WNP, discard the edges that do not exceed their weight threshold and typically perform a shallow pruning that retains high recall [22]. The *cardinality-based* schemes, CEP and CNP, rank the edges of the blocking graph in descending order of weight and retain a specific number of the top ones. For example, if CEP retained the 4 top-weighted edges of the graph in Figure 2(a), it would produce the pruned graph of Figure 2(b), too. Usually, CEP and CNP perform deeper pruning than WEP and WNP, trading higher precision for lower recall [22].

Applications of Entity Resolution. Based on their performance requirements, we distinguish ER applications into two categories:

(i) The *efficiency-intensive* applications aim to minimize the response time of ER, while detecting the vast majority of the duplicates. More formally, their goal is to maximize precision (*PQ*) for a recall (*PC*) that exceeds 0.80. To this category belong real-time applications or applications with limited temporal resources, such as Pay-as-you-go ER [26], entity-centric search [25] and crowd-sourcing ER [6]. Ideally, their goal is to identify a new pair of duplicate entities with every executed comparison.

(ii) The *effectiveness-intensive* applications can afford a higher response time in order to maximize recall. At a minimum, recall (*PC*) should not fall below 0.95. Most of these applications correspond to off-line batch processes like data cleaning in data warehouses, which practically call for almost perfect recall [2]. Yet, higher precision (*PQ*) is pursued even in off-line applications so as to ensure that they scale to voluminous datasets.

Meta-blocking accommodates the effectiveness-intensive applications through the weight-based pruning schemes (WEP, WNP) and the efficiency-intensive applications through the cardinality-based schemes (CEP, CNP).

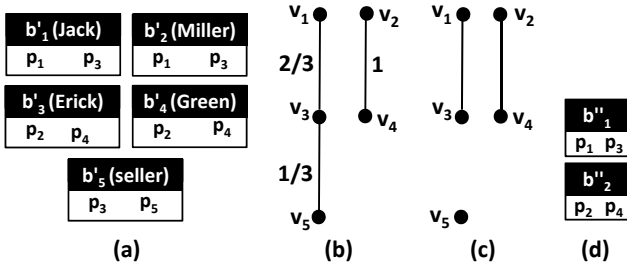

Figure 6: (a) The block collection produced by applying Block Filtering to the blocks in Figure 1(b), (b) the corresponding blocking graph, (c) the pruned blocking graph produced by WEP, and (d) the corresponding restructured block collection.

4. TIME EFFICIENCY IMPROVEMENTS

We now propose two methods for accelerating the processing of Meta-blocking, minimizing its *OTime*: (i) Block Filtering, which operates as a pre-processing step that reduces the size of the blocking graph, and (ii) Optimized Edge Weighting, which minimizes the computational cost for the weighting of individual edges.

4.1 Block Filtering

This approach is based on the idea that each block has a different importance for every entity profile it contains. For example, a block with thousands of profiles is usually superfluous for most of them, but it may contain a couple of matching entity profiles that do not co-occur in another block; for them, this particular block is indispensable. Based on this principle, Block Filtering restructures a block collection by removing profiles from blocks, in which their presence is not necessary. The *importance* of a block b_k for an individual entity profile $p_i \in b_k$ is implicitly determined by the maximum number of blocks p_i participates in.

Continuing our example with the blocks in Figure 1(b), assume that their importance is inversely proportional to their id; that is, b_1 and b_8 are the most and the least important blocks, respectively. A possible approach to Block Filtering would be to remove every entity profile from the least important of its blocks, i.e., the one with the largest block id. The resulting block collection appears in Figure 6(a). We can see that Block Filtering reduces the 15 original comparisons to just 5. Yet, there is room for further improvements, due to the presence of 2 redundant comparisons, one in b'_2 and another one in b'_4 , and 1 superfluous in block b'_5 . Using the JS weighting scheme, the graph corresponding to these blocks is presented in Figure 6(b) and the pruned graph produced by WEP appears in Figure 6(c). In the end, we get the 2 matching comparisons in Figure 6(d). This is a significant improvement over the 5 comparisons in Figure 2(c), which were produced by applying the same pruning scheme directly to the blocks of Figure 1(b).

In more detail, the functionality of Block Filtering is outlined in Algorithm 1. First, it orders the blocks of the input collection B in descending order of importance (Line 3). Then, it determines the maximum number of blocks per entity profile (Line 4). This requires an iteration over all blocks in order to count the block assignments per entity profile. Subsequently, it iterates over all blocks in the specified order (Line 5) and over all profiles in each block (Line 6). The profiles that have more block assignments than their threshold are discarded, while the rest are retained in the current block (Lines 7-10). In the end, the current block is retained only if it still contains at least two entity profiles (Lines 11-12).

The time complexity of this procedure is dominated by the sorting of blocks, i.e., $O(|B| \log |B|)$. Its space complexity is linear with respect to the size of the input, $O(|E|)$, because it maintains a threshold and a counter for every entity profile.

Algorithm 1: Block Filtering.

Input: B the input block collection
Output: B' the restructured block collection

```

1  $B' \leftarrow \{\}$ ;
2  $\text{counter}[] \leftarrow \{\}$ ; // count blocks per profile
3  $\text{orderBlocks}(B)$ ; // sort in descending importance
4  $\text{maxBlocks}[] \leftarrow \text{getThresholds}(B)$ ; // limit per profile
5 foreach  $b_k \in B$  do // check all blocks
6   foreach  $p_i \in b_k$  do // check all profiles
7     if  $\text{counter}[i] > \text{maxBlocks}[i]$  then
8        $b_k \leftarrow b_k \setminus p_i$ ; // remove profile
9     else
10       $\text{counter}[i]++$ ; // increment counter
11 if  $|b_k| > 1$  then // retain blocks with
12    $B' \leftarrow B' \cup b_k$ ; // at least 2 profiles
13 return  $B'$ ;

```

Figure 7: (a) Using Block Filtering for pre-processing the blocking graph of Meta-blocking, and (b) using Block Filtering as a graph-free Meta-blocking method.

The performance of Block Filtering is determined by two factors:

(i) The criterion that specifies the importance of a block b_i . This can be defined in various ways and ideally should be different for every profile in b_i . For higher efficiency, though, we use a criterion that is common for all profiles in b_i . It is also generic, applying to any block collection, independently of the underlying ER task or the schema heterogeneity. This criterion is the cardinality of b_i , $|b_i|$, presuming that the less comparisons a block contains, the more important it is for its entities. Thus, Block Filtering sorts a block collection from the smallest block to the largest one.

(ii) The *filtering ratio* (r) that determines the maximum number of block assignments per profile. It is defined in the interval $[0, 1]$ and expresses the portion of blocks that are retained for each profile. For example, $r=0.5$ means that each profile remains in the first half of its associated blocks, after sorting them in ascending cardinality. We experimentally fine-tune this parameter in Section 6.2.

Instead of a local threshold per entity profile, we could apply the same global threshold to all profiles. Preliminary experiments, though, demonstrated that this approach exhibits low performance, as the number of blocks associated with every profile varies largely, depending on the quantity and the quality of information it contains. This is particularly true for Clean-Clean ER, where E_1 and E_2 usually differ largely in their characteristics. Hence, it is difficult to identify the break-even point for a global threshold that achieves a good balance between recall and precision for all profiles.

Finally, it is worth noting that Block Filtering can be used in two fundamentally different ways, which are compared in Section 6.4.

(i) As a pre-processing method that prunes the blocking graph before applying Meta-blocking – see Figure 7(a).

(ii) As a graph-free Meta-blocking method that is combined only with Comparison Propagation – see Figure 7(b).

The latter workflow skips the blocking graph, operating on the level of individual profiles instead of profile pairs. Thus, it is expected to be significantly faster than all graph-based algorithms. If it achieves higher precision, as well, it outperforms the graph-based workflow in all respects, rendering the blocking graph unnecessary.

Algorithm 2: Original Edge Weighting.

Input: B the input block collection
Output: W the set of edge weights

```
1  $W \leftarrow \{\}$ ;  
2  $EI \leftarrow \text{buildEntityIndex}(B)$ ;  
3 foreach  $b_k \in B$  do // check all blocks  
4   foreach  $c_{i,j} \in b_k$  do // check all comparisons  
5      $B_i \leftarrow EI.\text{getBlockList}(p_i)$ ;  
6      $B_j \leftarrow EI.\text{getBlockList}(p_j)$ ;  
7      $\text{commonBlocks} \leftarrow 0$ ;  
8     foreach  $m \in B_i$  do  
9       foreach  $n \in B_j$  do  
10        if  $m < n$  then break; // repeat until  
11        if  $n < m$  then continue; // finding common id  
12        if  $\text{commonBlocks} = 0$  then // 1st common id  
13          if  $m \neq k$  then // it violates LeCoBI  
14            break to next comparison;  
15         $\text{commonBlocks}++$ ;  
16    $w_{i,j} \leftarrow \text{calculateWeight}(\text{commonBlocks}, B_i, B_j)$ ;  
17    $W \leftarrow W \cup \{w_{i,j}\}$ ;  
18 return  $W$ ;
```

4.2 Optimized Edge Weighting

A complementary way of speeding up Meta-blocking is to accelerate its bottleneck, i.e., the estimation of edge weights. Intuitively, we want to minimize the computational cost of the procedure that derives the weight from every individual edge. Before we explain in detail our solution, we give some background, by describing how the existing Edge Weighting algorithm operates.

The blocking graph cannot be materialized in memory in the scale of million nodes and billion edges. Instead, it is implemented implicitly. The key idea is that every edge $e_{i,j}$ in the blocking graph G_B corresponds to a non-redundant comparison $c_{i,j}$ in the block collection B . In other words, a comparison $c_{i,j}$ in $b_k \in B$ defines an edge $e_{i,j}$ in G_B as long as it satisfies the LeCoBI condition (see Section 2). The condition is checked with the help of the Entity Index during the core process that derives the blocks shared by p_i and p_j .

In more detail, the original implementation of Edge Weighting is outlined in Algorithm 2. Note that B_i stands for the *block list* of p_i , i.e., the set of block ids associated with p_i , sorted from the smallest to the largest one. The core process appears in Lines 7-15 and relies on the established process of Information Retrieval for intersecting the posting lists of two terms while answering a keyword query [18]: it iterates over the blocks lists of two co-occurring profiles in parallel, incrementing the counter of common blocks for every id they share (Line 15). This process is terminated in case the first common block id does not coincide with the id of the current block b_k , thus indicating a redundant comparison (Lines 12-14).

Our observation is that since this procedure is repeated for every comparison in B , a more efficient implementation would significantly reduce the run time of Meta-blocking. To this end, we develop a filtering technique inspired by similarity joins [14].

Prefix Filtering [3, 14] is a prominent method, which prunes dissimilar pairs of strings with the help of the minimum similarity threshold t that is determined *a-priori*; t can be defined with respect to various similarity metrics that are essentially equivalent, due to a set of transformations [14]. Without loss of generality, we assume in the following that t is normalized in $[0, 1]$, just like the edge weights, and that it expresses a Jaccard similarity threshold.

Adapted to edge weighting, Prefix Filtering represents every profile p_i by the $\lfloor (1-t) \cdot |B_i| \rfloor + 1$ smallest blocks of B_i . The idea is that pairs having disjoint representations cannot exceed the similarity

Algorithm 3: Optimized Edge Weighting.

Input: B the input block collection, E the input entity collection
Output: W the set of edge weights

```
1  $W \leftarrow \{\}$ ;  $\text{commonBlocks}[] \leftarrow \{\}$ ;  $\text{flags}[] \leftarrow \{\}$ ;  
2  $EI \leftarrow \text{buildEntityIndex}(B)$ ;  
3 foreach  $p_i \in E$  do // check all profiles  
4    $B_i \leftarrow EI.\text{getBlockList}(p_i)$ ;  
5    $\text{neighbors} \leftarrow \{\}$ ; // set of co-occurring profiles  
6   foreach  $b_k \in B_i$  do // check all associated blocks  
7     foreach  $p_j (\neq p_i) \in b_k$  do // co-occurring profile  
8       if  $\text{flags}[j] \neq i$  then  
9          $\text{flags}[j] = i$ ;  
10         $\text{commonBlocks}[j] = 0$ ;  
11         $\text{neighbors} \leftarrow \text{neighbors} \cup \{p_j\}$ ;  
12         $\text{commonBlocks}[j]++$ ;  
13   foreach  $p_j \in \text{neighbors}$  do  
14      $B_j \leftarrow EI.\text{getBlockList}(p_j)$ ;  
15      $w_{i,j} \leftarrow \text{calculateWeight}(\text{commonBlocks}[j], B_i, B_j)$ ;  
16      $W \leftarrow W \cup \{w_{i,j}\}$ ;  
17 return  $W$ ;
```

threshold t . For example, for $t=0.8$ an edge $e_{i,j}$ could be pruned using 1/5 of B_i and B_j , thus speeding up the nested loops in Lines 8-9 of Algorithm 2. Yet, there are 3 problems with this approach:

(i) For the weight-based algorithms, the pruning criterion t can only be determined *a-posteriori* – after averaging all edge weights in the entire graph (WEP), or in a node neighborhood (WNP). As a result, the optimizations of Prefix Filtering apply only to the pruning phase of WEP and WNP and not to the initial construction of the blocking graph.

(ii) For the cardinality-based algorithms CEP and CNP, t equals the minimum edge weight in the sorted stack with the top-weighted edges. Thus, its value is continuously modified and cannot be used for a-priori building optimized entity representations.

(iii) Preliminary experiments demonstrated that t invariably takes very low values, below 0.1, for all combinations of pruning algorithms and weighting schemes. These low thresholds force all versions of Prefix Filtering to consider the entire block lists B_i and B_j as entity representations, thus ruining their optimizations.

For these reasons, we propose a novel implementation that is independent of the similarity threshold t . Our approach is outlined in Algorithm 3. Instead of iterating over all comparisons in B , it iterates over all input profiles in E (Line 3). The core procedure in Lines 6-12 works as follows: for every profile p_i , it iterates over all co-occurring profiles in the associated blocks and records their frequency in an array. At the end of the process, $\text{commonBlocks}[j]$ indicates the number of blocks shared by p_i and p_j . This information is then used in Lines 13-16 for estimating the weight $w_{i,j}$. This method is reminiscent of *ScanCount* [16]. Note that the array flags helps us to avoid reallocating memory for commonBlocks in every iteration, a procedure that would be costly, due to its size, $|E|$ [16]; neighbors is a hash set that stores the unique profiles that co-occur with p_i , gathering the distinct neighbors of node n_i in the blocking graph without evaluating the LeCoBI condition.

4.3 Discussion

The average time complexity of Algorithm 2 is $O(2 \cdot BPE \cdot \|B\|)$, where $BPE(B) = \sum_{b \in B} |b| / |E|$ is the average number of blocks associated with every profile in B ; $2 \cdot BPE$ corresponds to the average computational cost of the nested loops in Lines 8-9, while $\|B\|$ stems from the nested loops in Lines 3-4, which iterate over all comparisons in B .

Block Filtering improves this time complexity in two ways:

(i) It reduces $\|B\|$ by discarding a large part of the redundant and superfluous comparisons in B .

(ii) It reduces $2 \cdot BPE$ to $2 \cdot r \cdot BPE$ by removing every profile from $(1-r) \cdot 100\%$ of its associated blocks, where r is the filtering ratio.⁴

The computational cost of Algorithm 3 is determined by two procedures that yield an average time complexity of $O(\|B\| + |\bar{v}| \cdot |E|)$:

(i) The three nested loops in Lines 3-7. For every block b , these loops iterate over $|b|-1$ of its entity profiles (i.e., over all profiles except p_i) for $|b|$ times – once for each entity profile. Therefore, the process in Lines 8-12 is repeated $|b| \cdot (|b|-1) = \|B\|$ times and the overall complexity of the three nested loops is $O(\|B\|)$.

(ii) The loop in Lines 13-16. Its cost is analogous to the average node degree $|\bar{v}|$, i.e., the average number of neighbors per profile. It is repeated for every profile and, thus, its overall cost is $O(|\bar{v}| \cdot |E|)$.

Comparing the two algorithms, we observe that the optimized implementation minimizes the computational cost of the process that is applied to each comparison: instead of intersecting the associated block lists, it merely updates 2-3 cells in 2 arrays and adds an entity id in the set of neighboring profiles. The former process involves two nested loops with an average cost of $O(2 \cdot BC)$, while the latter processes have a constant complexity, $O(1)$. Note that Algorithm 3 incorporates the loop in Lines 13-16, which has complexity of $O(|\bar{v}| \cdot |E|)$. In practice, though, this is considerably lower than both $O(2 \cdot BPE \cdot \|B\|)$ and $O(\|B\|)$, as we show in Section 6.3.

5. PRECISION IMPROVEMENTS

We now introduce two new pruning algorithms that significantly enhance the effectiveness of Meta-blocking, increasing precision for similar levels of recall: (i) Redefined Node-centric Pruning, which removes all redundant comparisons from the restructured blocks of CNP and WNP, and (ii) Reciprocal Pruning, which infers the most promising matches from the reciprocal links of the directed pruned blocking graphs of CNP and WNP.

There are several reasons why we exclusively focus on improving the precision of CNP and WNP:

(i) Node-centric algorithms are quite robust to recall, since they retain the most likely matches for each node and, thus, guarantee to include every profile in the restructured blocks. Edge-centric algorithms do not provide such guarantees, because they retain the overall best edges from the entire graph.

(ii) Node-centric algorithms are more flexible, in the sense that their performance can be improved in generic, algorithmic ways. Instead, edge-centric algorithms improve their performance only with threshold fine-tuning. This approach, though, is application-specific, as it is biased by the characteristics of the block collection at hand. Another serious limitation is that some superfluous comparisons cannot be pruned without discarding part of the matching ones. For instance, the superfluous edge $e_{5,6}$ in Figure 2(a) has a higher weight than both matching edges $e_{1,3}$ and $e_{2,4}$.

(iii) There is more room for improvement in node-centric algorithms, because they exhibit lower precision than the edge-centric ones. They process every profile independently of the others and they often retain the same edge for both incident profiles, thus yielding redundant comparisons. They also retain more superfluous comparisons than the edge-centric algorithms in most cases [22]. As an example, consider Clean-Clean ER: every profile from both

Figure 8: (a) The undirected pruned blocking graph corresponding to the directed one Figure 5(a), and (b) the corresponding block collection.

entity collections retains its connections with several incident nodes, even though only one of them is matching with it.

Nevertheless, our experiments in Section 6.4 demonstrate that our new node-centric algorithms outperform the edge-centric ones, as well. They also cover both efficiency- and effectiveness-intensive ER applications, enhancing both CNP and WNP.

5.1 Redefined Node-centric Pruning

We can enhance the precision of both CNP and WNP without any impact on recall by discarding all the redundant comparisons they retain. Assuming that the blocking graph is materialized, a straightforward approach is to convert the directed pruned graph into an undirected one by connecting every pair of neighboring nodes with a single undirected edge – even if they are reciprocally linked. In the extreme case where every retained edge has a reciprocal link, this saves 50% more comparisons and doubles precision.

As an example, the directed pruned graph in Figure 5(a) can be transformed into the undirected pruned graph in Figure 8(a); the resulting blocks, which are depicted in Figure 8(b), reduce the retained comparisons from 9 to 5, while maintaining the same recall as the blocks in Figure 5(b): p_1-p_3 co-occur in b'_1 and p_2-p_4 in b'_4 .

Yet, it is impossible to materialize the blocking graph in memory in the scale of billions of edges. Instead, the graph is implicitly implemented as explained in Section 4.2. In this context, a straightforward solution for improving CNP and WNP is to apply Comparison Propagation to their output. This approach, though, entails a significant overhead, as it evaluates the LeCoBI condition for every retained comparison; on average, its total cost is $O(2 \cdot BPE \cdot \|B'\|)$.

The best solution is to redefine CNP and WNP so that Comparison Propagation is integrated into their functionality. The new implementations are outlined in Algorithms 4 and 5, respectively. In both cases, the processing consists of two phases:

(i) The first phase involves a node-centric functionality that goes through the nodes of the blocking graph and derives the pruning criterion from their neighborhood. A central data structure stores the top- k nearest neighbors (CNP) or the weight threshold (WNP) per node neighborhood. In total, this phase iterates twice over every edge of the blocking graph – once for each incident node.

(ii) The second phase operates in an edge-centric fashion that goes through all edges, retaining those that satisfy the pruning criterion for at least one of the incident nodes. Thus, every edge is retained at most once, even if it is important for both incident nodes.

In more detail, Redefined CNP iterates over all nodes of the blocking graph to extract their neighborhood and calculate the corresponding cardinality threshold k (Lines 2-4 in Algorithm 4). Then it iterates over the edges of the current neighborhood and places the top- k weighted ones in a sorted stack (Lines 5-8). In the second phase, it iterates over all edges and retains those contained in the sorted stack of either of the incident profiles (Lines 10-13).

Similarly, Redefined WNP first iterates over all nodes of the blocking graph to extract their neighborhood and to estimate the

⁴This seems similar to the effect of Prefix Filtering, but there are fundamental differences: (i) Prefix Filtering does not reduce the number of executed comparisons; it just accelerates their pruning. (ii) Prefix Filtering relies on a similarity threshold for pairs of profiles, while the filtering ratio r pertains to individual profiles.

Algorithm 4: Redefined Cardinality Node Pruning.

Input: (i) G_B^{in} the blocking graph, and
(ii) ct the function defining the local cardinality thresholds.
Output: G_B^{out} the pruned blocking graph

```

1 SortedStacks[]  $\leftarrow \{\}$ ; // sorted stack per node
2 foreach  $v_i \in V_B$  do // for every node
3    $G_{v_i} \leftarrow \text{getNeighborhood}(v_i, G_B)$ ;
4    $k \leftarrow ct(G_{v_i})$ ; // get local cardinality threshold
5   foreach  $e_{i,j} \in E_{v_i}$  do // add every adjacent edge
6     SortedStacks[i].push( $e_{i,j}$ ); // in sorted stack
7     if  $k < \text{SortedStacks[i].size}()$  then
8       SortedStacks[i].pop(); // remove last edge
9  $E_B^{out} \leftarrow \{\}$ ; // the set of retained edges
10 foreach  $e_{i,j} \in E_B$  do // for every edge
11   if  $e_{i,j} \in \text{SortedStacks[i]}$ 
12   OR  $e_{i,j} \in \text{SortedStacks[j]}$  then // retain if in
13      $E_B^{out} \leftarrow E_B^{out} \cup \{e_{i,j}\}$ ; // top-k for either node
14 return  $G_B^{out} = \{V_B, E_B^{out}, WS\}$ ;

```

corresponding weight threshold (Lines 2-4 in Algorithm 5). Then, it iterates once over all edges and retains those exceeding the weight thresholds of either of the incident nodes (Lines 6-9).

For both algorithms, the function *getNeighborhood* in Line 3 implements the Lines 4-16 of Algorithm 3. Note also that both algorithms use the same configuration as their original implementations: $k = \lfloor \sum_{b \in B} |b| / |E| - 1 \rfloor$ for Redefined CNP and the average weight of each node neighborhood for Redefined WNP. Their time complexity is $O(|V_B| \cdot |E_B|)$ in the worst-case of a complete blocking graph, and $O(|E_B|)$ in the case of a sparse graph, which typically appears in practice. Their space complexity is dominated by the requirements of Entity Index and the number of retained comparisons, i.e., $O(BPE \cdot |V_B| + |B'|)$, on average.

5.2 Reciprocal Node-centric Pruning

This approach treats the redundant comparisons retained by CNP and WNP as strong indications for profile pairs with high chances of matching. As explained above, these comparisons correspond to reciprocal links in the blocking graph. For example, the edges $e_{1,3}^{\rightarrow}$ and $e_{3,1}^{\rightarrow}$ in Figure 5(a) indicate that p_1 is highly likely to match with p_3 and vice versa, thus reinforcing the likelihood that the two profiles are duplicates. Based on this rationale, Reciprocal Pruning retains one comparison for every pair of profiles that are reciprocally connected in the directed pruned blocking graph of the original node-centric algorithms; profiles that are connected with a single edge, are not compared in the restructured block collection.

In our example, Reciprocal Pruning converts the directed pruned blocking graph in Figure 5(a) into the undirected pruned blocking graph in Figure 9(a). The corresponding restructured blocks in Figure 9(b) contain just 4 comparisons, one less than the blocks in Figure 8(b). Compared to the blocks in Figure 5(b), the overall efficiency is significantly enhanced at no cost in recall.

In general, Reciprocal Pruning yields restructured blocks with no redundant comparisons and less superfluous ones than both the original and the redefined node-centric pruning. In the worst case, all pairs of nodes are reciprocally linked and Reciprocal Pruning coincides with Redefined Node-centric Pruning. In all other cases, its precision is much higher, while its impact on recall depends on the strength of co-occurrence patterns in the blocking graph.

Reciprocal Pruning yields two new node-centric algorithms: Reciprocal CNP and Reciprocal WNP. Their functionality is almost

Algorithm 5: Redefined Weighted Node Pruning.

Input: (i) G_B^{in} the blocking graph, and
(ii) wt the function defining the local weight thresholds.
Output: G_B^{out} the pruned blocking graph

```

1 weights[]  $\leftarrow \{\}$ ; // thresholds per node
2 foreach  $v_i \in V_B$  do // for every node
3    $G_{v_i} \leftarrow \text{getNeighborhood}(v_i, G_B)$ ;
4   weights[i]  $\leftarrow wt(G_{v_i})$ ; // get local threshold
5  $E_B^{out} \leftarrow \{\}$ ; // the set of retained edges
6 foreach  $e_{i,j} \in E_B$  do // for every edge
7   if weights[i]  $\leq e_{i,j}.weight$ 
8   OR weights[j]  $\leq e_{i,j}.weight$  then // retain if it
9      $E_B^{out} \leftarrow E_B^{out} \cup \{e_{i,j}\}$ ; // exceeds either threshold
10 return  $G_B^{out} = \{V_B, E_B^{out}, WS\}$ ;

```

Figure 9: (a) The pruned blocking graph produced by applying Reciprocal Pruning to the graph in Figure 5(a), and (b) the restructured blocks.

identical to Redefined CNP and Redefined WNP, respectively. The only difference is that they use conjunctive conditions instead of disjunctive ones: the operator OR in Lines 11-12 and 7-8 of Algorithms 4 and 5, respectively, is replaced by the operator AND. Both algorithms use the same pruning criteria as redefined methods, while sharing the same average time and space complexities: $O(|E_B|)$ and $O(BPE \cdot |V_B| + |B'|)$, respectively.

6. EXPERIMENTAL EVALUATION

We now examine the performance of our techniques through a series of experiments. We present their setup in Section 6.1 and in Section 6.2, we fine-tune Block Filtering, assessing its impact on blocking effectiveness. Its impact on time efficiency is measured in Section 6.3 together with that of Optimized Edge Weighting. Section 6.4 assess the effectiveness of our new pruning algorithms and compares them to state-of-the-art block processing methods.

6.1 Setup

We implemented our approaches in Java 8 and tested them on a desktop machine with Intel i7-3770 (3.40GHz) and 16GB RAM, running Ubuntu 15.04 (kernel version 3.19.0). We repeated all time measurements 10 times and report the average value so as to minimize the effect of external parameters.

Datasets. In our experiments, we use 3 real-world entity collections. They are established benchmarks [15, 21, 24] with significant variations in their size and characteristics. They pertain to Clean-Clean ER, but are used for Dirty ER, as well; we simply merge their clean entity collections into a single one that contains duplicates in itself. In total, we have 6 block collections that lay the ground for a thorough experimental evaluation of our techniques.

To present the technical characteristics of the entity collections, we use the following notation: $|E|$ stands for the number of profiles they contain, $|D(E)|$ for the number of existing duplicates, $|N|$ for the number of distinct attribute names, $|P|$ for the total number of name-value pairs, $|\bar{p}|$ for the mean number of name-value pairs

Table 2: Technical characteristics of the entity collections. For D_{3C} and D_{3D} , $RT(E)$ was estimated from the average time required for comparing two of its entity profiles: 0.03 msec.

per profile, $|E|$ for the number of comparisons executed by the brute-force approach and $RT(E)$ for its resolution time; in line with $RTime(B)$, $RT(E)$ is computed using the Jaccard similarity of all tokens in the values of two profiles as the entity matching method.

Tables 2(a) and (b) present the technical characteristics of the real entity collections for Clean-Clean and Dirty ER, respectively. D_{1C} contains bibliographic data from DBLP (www.dblp.org) and Google Scholar (<http://scholar.google.gr>) that were matched manually [15, 24]. D_{2C} matches movies from IMDB (imdb.com) and DBPedia (<http://dbpedia.org>) based on their ImdbId [22, 23]. D_{3C} involves profiles from two snapshots of English Wikipedia (<http://en.wikipedia.org>) Infoboxes, which were automatically matched based on their URL [22, 23]. For Dirty ER, the datasets D_{xD} with $x \in [1, 6]$ were derived by merging the profiles of the individually clean collections that make up D_{xC} , as explained above.

Measures. To assess the *effectiveness* of a restructured block collection B' , we use four established measures [4, 5, 22]: (i) its cardinality $||B'||$, i.e., total number of comparisons, (ii) its recall $PC(B')$, (iii) its precision $PQ(B')$, and (iv) its *Reduction Ratio* (RR), which expresses the relative decrease in its cardinality in comparison with the original block collection, B : $RR(B, B') = 1 - ||B'||/||B||$. The last three measures take values in the interval $[0, 1]$, with higher values, indicating better effectiveness; the opposite is true for $||B'||$, as effectiveness is inversely proportional to its value (cf. Section 3).

To assess the *time efficiency* of a restructured block collection B' , we use the two measures that were defined in Section 3: (i) its *Overhead Time* $OTime(B')$, which measures the time required by Meta-blocking to derive it from the input block collection, and (ii) its *Resolution Time* $RTime(B')$, which adds to $OTime(B')$ the time taken to apply an entity matching method to all comparisons in B' .

6.2 Block Collections

Original Blocks. From all datasets, we extracted a redundancy-positive block collection by applying Token Blocking [21]. We also applied Block Purging [21] in order to discard those blocks that

Figure 10: The effect of Block Filtering's ratio r on the blocks of D_{5C} and D_{5D} with respect to RR and PC .

contained more than half of the input entity profiles. The technical characteristics of the resulting block collections are presented in Table 1(a). Remember that $|V_B|$ and $|E_B|$ stand for the order and the size of the corresponding blocking graph, respectively. RR has been computed with respect to $|E|$ in Table 2, i.e., $RR = 1 - ||B'||/||E||$.

We observe that all block collections exhibit nearly perfect recall, as their PC consistently exceeds 0.98. They also convey significant gains in efficiency, executing an order of magnitude less comparisons than the brute-force approach ($RR > 0.9$) in most cases. They reduce the resolution time to a similar extent, due to their very low $OTime$. Still, their precision is significantly lower than 0.01 in all cases. This means that on average, more than 100 comparisons have to be executed in order to identify a new pair of duplicates. The corresponding blocking graphs vary significantly in size, ranging from tens of thousands edges to tens of billions, whereas their order ranges from few thousands nodes to few millions.

Note that we experimented with additional redundancy-positive blocking methods, such as Q-grams Blocking. All of them involved a schema-agnostic functionality that tackles effectively the schema heterogeneity. They all produced blocks with similar characteristics as Token Blocking and are omitted for brevity. In general, the outcomes of our experiments are independent of the schema-agnostic, redundancy-positive methods that yield the input blocks.

Block Filtering. Before using Block Filtering, we have to fine-tune its *filtering ratio* r , which determines the portion of the most important blocks that are retained for each profile. To examine its effect, we measured the performance of the restructured blocks using all values of r in $[0.05, 1]$ with a step of 0.05. We consider two evaluation measures: recall (PC) and reduction ratio (RR).

Figure 10 presents the evolution of both measures over the original blocks of D_{5C} and D_{5D} – the other datasets exhibit similar patterns and are omitted for brevity. We observe that there is a clear trade-off between RR and PC : the smaller the value of r , the less blocks are retained for each profile and the lower is the total cardinality of the restructured blocks $||B'||$, thus increasing RR ; this reduces the number of detected duplicates, thus decreasing PC . The opposite is true for large values of r . Most importantly, Block Filtering exhibits a robust performance with respect to r , with small

Table 3: Performance of the existing pruning schemes, averaged across all weighting schemes, before and after Block Filtering.

variations in its value leading to small differences in RR and PC .

To use Block Filtering as a pre-processing method, we should set its ratio to a value that increases precision at a low cost in recall. We quantify this constraint by requiring that r decreases PC by less than 0.5%, while maximizing RR and, thus, PQ . The ratio that satisfies this constraint across all datasets is $r=0.80$. Table 1(b) presents the characteristics of the restructured block collections corresponding to this configuration. Note that RR has been computed with respect to the cardinality of the original blocks.

We observe that the number of blocks is almost the same as in Table 1(a). Yet, their total cardinality is reduced by 64% to 75%, while recall is reduced by less than 0.5% in most cases. As a result, PQ rises from 2.7 to 4.0 times, but still remains far below 0.01. There is an insignificant increase in $OTime$ and, thus, $RTime$ decreases to the same extent as RR . The same applies to the order of the blocking graph $|E_B|$, while its size $|V_B|$ remains almost the same. Finally, BPE is reduced by $(1-r) \cdot 100\% = 20\%$ across all datasets.

6.3 Time Efficiency Improvements

Table 3 presents the performance of the four existing pruning schemes, averaged across all weighting schemes. Their original performance appears in the left part, while the right part presents their performance after Block Filtering.

Original Performance. We observe that CEP reduces the executed comparisons by 1 to 3 orders of magnitude for the smallest and the largest datasets, respectively. It increases precision (PQ) to a similar extent at the cost of much lower recall in most of the cases. This applies particularly to Dirty ER, where PC drops consistently below 0.80, the minimum acceptable recall of efficiency-intensive ER applications. The reason is that Dirty ER is more difficult than Clean-Clean ER, involving much larger blocking graphs with many more noisy edges between non-matching entity profiles.

CNP is more robust to recall than CEP, as its PC lies well over 0.80 across all datasets. Its robustness stems from its node-centric functionality, which retains the best edges per node, instead of the globally best ones. This comes, though, at the cost of a much higher computational cost: its overhead time is larger than that of CEP by 44%, on average. Further, CNP retains almost twice as many comparisons and yields a slightly lower precision than CEP.

For WEP, we observe that its recall consistently exceeds 0.95, the minimum acceptable PC of effectiveness-intensive ER applications. At the same time, it executes almost an order of magni-

tude less comparisons than the original blocks in Table 1(a) and enhances PQ to a similar extent. These patterns apply to all datasets.

Finally, WNP saves 60% of the brute-force comparisons, on average, retaining twice as many comparisons as WEP. Its recall remains well over 0.95 across all datasets, exceeding that of WEP to a minor extent. As a result, its precision is half that of WEP, while its overhead time is slightly higher.

In summary, these experiments verify previous findings about the relative performance of pruning schemes [22]: the cardinality-based ones excel in precision, being more suitable for efficiency-intensive ER applications, while the weight-based schemes excel in recall, being more suitable for effectiveness-intensive applications. In both cases, the node-centric algorithms trade higher recall for lower precision and higher overhead.

Block Filtering. Examining the effect of Block Filtering in the right part of Table 3, we observe two patterns:

(i) Its impact on overhead time depends on the dataset at hand, rather than the pruning scheme applied on top of it. In fact, $OTime$ is reduced by 65% (D_{1C}) to 78% (D_{1D}), on average, across all pruning schemes. This is close to RR and the reduction in the order of the blocking graph $|E_B|$, but higher than them, because Block Filtering additionally reduces BPE by 20%.

(ii) Its impact on blocking effectiveness depends on the type of the pruning criterion used by Meta-blocking. For cardinality thresholds, Block Filtering conveys a moderate decrease in the retained comparisons, with $\|B'\|$ dropping by 20%, on average. The reason is that both CEP and CNP use thresholds that are proportional to BPE , which is reduced by $(1-r) \cdot 100\%$. At the same time, their recall is either reduced to a minor extent ($<2\%$), or increases by up to 10%. The latter case appears in half the datasets and indicates that Block Filtering cleans the blocking graph from noisy edges, enabling CEP and CNP to identify more duplicates with fewer retained comparisons.

For weight thresholds, Block Filtering reduces the number of retained comparisons to a large extent: $\|B'\|$ drops by 62% to 71% for both WEP and WNP. The reason is that their pruning criteria depends directly on the size and the structure of the blocking graph. At the same time, their recall gets lower by less than 3% in all cases, an affordable reduction that is caused by two factors: (i) Block Filtering discards some matching edges itself, and (ii) Block Filtering reduces the extent of co-occurrence for some matching entity profiles, thus lowering the weight of their edges.

Table 5: $OTime$ of Optimized Edge Weighting for each pruning scheme, averaged across all weighting schemes, over the datasets in Table 1(b), i.e., after Block Filtering.

We can conclude that Block Filtering enhances the scalability of Meta-blocking to a significant extent, accelerating the processing of all pruning schemes almost by 4 times, on average. It also achieves much higher precision, while its impact on recall is either negligible or beneficial. Thus, it constitutes an indispensable pre-processing step for Meta-blocking. For this reason, the following experiments are carried out on top of Block Filtering.

Optimized Edge Weighting. Table 5 presents the overhead time of the four pruning schemes when combined with Block Filtering and Optimized Edge Weighting (cf. Algorithm 3). Comparing it with $OTime$ in the right part of Table 3, we observe significant enhancements in efficiency. Again, they depend on the dataset at hand, rather than the pruning scheme. In fact, the higher the BPE of a dataset after Block Filtering, the larger is the reduction in overhead time: $OTime$ is reduced by 19% for D_{1C} , where BPE takes the lowest value across all datasets (3.63), and by 92% for D_{2D} , where BPE takes the highest one (26.29). The reason is that Optimized Edge Weighting minimizes the computational cost of the process that is applied to every comparison by Original Edge Weighting (cf. Algorithm 2) from $O(2 \cdot BPE)$ to $O(1)$.

Also interesting is the comparison between $OTime$ in Table 5 and $OTime$ in the left part of Table 3, i.e., before applying Block Filtering to the input blocks. On average, across all datasets and pruning schemes, $OTime$ is reduced by 87%, which is almost an order of magnitude. Again, the lowest (72%) and the highest (98%) average reductions correspond to D_{1C} and D_{2D} , respectively, which exhibit the minimum and the maximum BPE before Block Filtering. We can conclude, therefore, that the two efficiency optimizations are complementary and indispensable for scalable Meta-blocking.

6.4 Precision Improvements

To estimate the performance of Redefined and Reciprocal Node-centric Pruning, we applied the four pruning schemes they yield to the datasets in Table 1(b). Their performance appears in Table 4.

Cardinality-based Pruning. Starting with Redefined CNP, we observe that it maintains the recall of the original CNP, while conveying a moderate increase in efficiency. On average, across all weighting schemes and datasets, it retains 18% less comparisons, increasing PQ by 1.2 times. With respect to $OTime$, there is no clear winner, as the implementation of both algorithms is highly similar, relying on Optimized Edge Weighting. Hence, the original CNP is just 2% faster, on average, because it does not store all

retained edges per node in memory.

For Reciprocal CNP, $OTime$ is practically identical with that of Redefined CNP, as they only differ in a single operator. Yet, Reciprocal CNP consistently achieves the highest precision among all versions of CNP at the cost of the lowest recall. On average, it retains 82% and 78% less comparisons than CNP and Redefined CNP, respectively, while increasing precision by 7.9 and 6.9 times, respectively; it also decreases recall by 11%, but exceeds the minimum acceptable PC for efficiency-intensive applications (0.80) to a significant extent in most cases. The only exception is D_{2D} , where PC drops below 0.80 for all weighting schemes. Given that the corresponding Clean-Clean ER dataset (D_{2C}) exhibits much higher PC , the poor recall for D_{2D} is attributed to highly similar (i.e., noisy) entity profiles in one of the duplicate-free entity collections.

It is worth comparing at this point the new pruning schemes with their edge-centric counterpart: CEP coupled with Block Filtering (see right part of Table 3). We observe three patterns: (i) On average, CEP keeps 33% less comparisons than Redefined CNP, but lowers recall by 18%. Its recall is actually so low in most datasets that Redefined CNP achieves higher precision in all cases except D_{1C} and D_{2C} . (ii) Reciprocal CNP typically outperforms CEP in all respects of effectiveness. On average, it executes 67% less comparisons, while increasing recall by 8%. D_{1C} is the exception that proves this rule: Reciprocal CNP saves more than an order of magnitude more comparisons, but CEP achieves slightly higher recall. (iii) The overhead time of CEP is lower by 44%, on average, than both algorithms, because it iterates once instead of twice over all edges in the blocking graph.

On the whole, we can conclude that Reciprocal CNP offers the best choice for efficiency-intensive applications, as it consistently achieves the highest precision among all cardinality-based pruning schemes with $PC \geq 0.8$. However, in datasets with high levels of noise, where many entity profiles share the same information, Redefined CNP should be preferred; it is more robust to recall than CEP and Reciprocal CNP, while saving 30% more comparisons than CNP. In any case, Block Filtering is indispensable.

Weight-based Pruning. As expected, Redefined WNP maintains the same recall as the original implementation of WNP, while conveying major enhancements in efficiency. On average, across all weighting schemes and datasets, it reduces the retained comparisons by 28% and increases precision by 1.5 times. It is also faster than WNP by 7%, but in practice, the method with the lowest $OTime$ varies across the datasets.

Reciprocal WNP performs a deeper pruning that consistently trades a lower number of executed comparisons for a lower recall. On average, it reduces the total cardinality of WNP by 72% and the recall by 2%. Its mean PC drops slightly below 0.95 in D_{2C} , but this does not apply to all weighting schemes; two of them exceed the minimum acceptable recall of effectiveness-intensive applications even for this dataset. As a result, Reciprocal WNP enhances the precision of WNP by 3.9 times. Its overhead is slightly lower than

$OTime(B')$	76 msec	2 sec	1.9 hrs	5 sec	1 min	11.1 hrs
(c) Iterative Blocking						

Table 6: Performance of the baseline methods over all datasets.

Redefined WNP, because it retains less comparisons in memory. Thus, it is faster than WNP by 9%, on average.

Compared to WEP, Redefined WNP exhibits lower precision, but is more robust to recall, maintaining PC well above 0.95 under all circumstances. In contrast, WEP violates this constraint in all datasets for at least one weighting scheme. Reciprocal WNP scores higher precision than WEP, while being more robust to recall, as well. For this reason, it is the optimal choice for effectiveness-intensive applications. Again, for datasets with high levels of noise, Redefined WNP should be preferred.

Baseline Methods. We now compare our techniques with the state-of-the-art block processing method Iterative Blocking [27] and with Graph-free Meta-blocking (see end of Section 4.1). The functionality of the former was optimized by ordering the blocks from the smallest to the largest cardinality; its functionality was further optimized for Clean-Clean ER by assuming the ideal case where two matching entities are not compared to other co-occurring entities after their detection. The configuration of Graph-free Meta-blocking was also optimized by setting r to the smallest values in $[0.05, 1.0]$ with a step of 0.05 that ensures a recall higher than 0.80 and 0.95 across all real datasets; this resulted in $r=0.25$ and $r=0.55$ for efficiency- and effectiveness-intensive applications, respectively. Table 6 presents the performance of the two methods.

Juxtaposing Efficiency-intensive Graph-free Meta-blocking and Reciprocal CNP, we notice a clear trade-off between precision and recall. The latter approach emphasizes PQ , retaining 85% less comparisons at the cost of 5% lower PC , on average. The only advantage of Graph-free Meta-blocking is its minimal overhead: its lightweight functionality is able to process datasets with millions of entities within few minutes even on commodity hardware. Similar patterns arise when comparing Reciprocal WNP with Effectiveness-intensive Graph-free Meta-blocking: the former executes 58% less comparisons at the cost of a 2% decrease in recall, thus achieving higher precision. This behaviour can be explained by the fine-grained functionality of Reciprocal Pruning: unlike Graph-free Meta-blocking, which operates on the level of individual entities, it considers pairwise comparisons, thus being more accurate in their pruning.

Compared to Iterative Blocking, Reciprocal WNP retains less comparisons by a whole order of magnitude at the cost of slightly lower recall. Thus, it achieves significantly higher precision. The overhead of Iterative Blocking is significantly lower in most cases, but it does not scale well to large datasets, even though Iterative Blocking does not involve a blocking graph. The reason is that it goes through the input block collection several times, updating the representation of the duplicate entities in all blocks that contain them, whenever a new match is detected.

7. CONCLUSIONS

In this paper, we introduced two techniques for boosting the efficiency of Meta-blocking along with two techniques for enhancing its effectiveness. Our thorough experimental analysis verified that in combination, our methods go well beyond the existing Meta-blocking techniques in all respects and simplify its configuration, depending on the data and the application at hand. For efficiency-intensive ER applications, Reciprocal CNP processes a large heterogeneous dataset with 3 millions entities and 80 billion comparisons within 2 hours even on commodity hardware; it also manages to retain recall and precision above 0.8 and 0.1, respectively. For effectiveness-intensive ER applications, Reciprocal WNP processes the same voluminous dataset within 5 hours on commodity hardware, while retaining recall above 0.95 and precision close to 0.01. In both cases, Block Filtering and Optimized Edge Weighting are indispensable. In the future, we plan to adapt our techniques for Enhanced Meta-blocking to Incremental Entity Resolution.

ABSTRACT

Exchange-repair semantics (or, XR-Certain semantics) is a recently proposed inconsistency-tolerant semantics in the context of data exchange. This semantics makes it possible to provide meaningful answers to target queries in cases in which a given source instance cannot be transformed into a target instance satisfying the constraints of the data exchange specification. It is known that computing the answers to conjunctive queries under XR-Certain semantics is a coNP-complete problem in data complexity. Moreover, this problem can be reduced in a natural way to cautious reasoning over stable models of a disjunctive logic program.

Here, we explore how to effectively perform XR-Certain query answering for practical data exchange settings by leveraging modern sophisticated solvers for disjunctive logic programming. We first present a new reduction, accompanied by an optimized implementation, of XR-Certain query answering to disjunctive logic programming. We then evaluate this approach on a benchmark that we introduce here and which is modeled after a practical data exchange problem in computational genomics. Specifically, we present a benchmark scenario that mimicks a portion of the UCSC Genome Browser data import process. Our initial results, based on real genomic data, suggest that the solvers we apply fail to take advantage of some critical exploitable structural properties of the specific instances at hand. We then develop an improved encoding to take advantage of these properties using techniques inspired by the notion of a repair envelope. The improved implementation utilizing these techniques computes query answers ten to one thousand times faster for large instances, and exhibits promising scalability with respect to the size of instances and the rate of target constraint violations.

1. INTRODUCTION

Data exchange is the task of transforming data structured under a source schema into data structured under a target schema in such a way that all constraints in a fixed set of source-to-target constraints and in a fixed set of target constraints are satisfied. During the past decade, there has been an extensive and multifaceted investigation of data exchange (see the monograph [1]). There are two main algorithmic problems in data exchange: the problem of materializing an instance that, together with a given source instance satisfies all constraints (such an instance is called a *solution* of the given source instance) and the problem of computing the *certain answers* to a query over the target schema, i.e., the intersection of the answers to the query over all solutions of a given source instance. In data exchange settings with a non-empty set of target constraints, it frequently happens that a given source instance has no solution. In particular, this may happen when the source instance at hand contains inconsistencies or conflicting information that is exposed by the target constraints. The standard data exchange frameworks are not able to provide meaningful answers to target queries in such circumstances; in fact, the certain answers to every target query trivialize. To address this problem and to give meaningful answers to target queries, we recently introduced the framework of *exchange-repair* semantics (or, XR-Certain semantics) [8]. This is an inconsistency-tolerant framework that is based on the notion of *source* repairs, where, informally, a source repair is a source instance that differs minimally from the original source data, but has a solution. In turn, source repairs give rise to the notion of the XR-Certain *answers* to target queries, which, by definition, are the intersection of the answers to the query over all solutions of all source repairs of the given source instance. It should be noted that inconsistency-tolerant semantics have also been investigated in the context of data integration (see, e.g., [7, 17]) and in the context of ontology-based data access (OBDA) (see, e.g., the recent survey [5]). In [9], which is the full version of [8], we provided a detailed comparison between the XR-Certain semantics and the inconsistency-tolerant semantics in these two other frameworks. In partic-

ular, we showed that, as regards consistent query answering, the exchange-repairs framework and the OBDA framework can simulate each other.

A data exchange task is specified using a *schema mapping* $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$, where \mathbf{S} is the source schema, \mathbf{T} is the target schema, Σ_{st} is a set of constraints between \mathbf{S} and \mathbf{T} , and Σ_t is a set of constraints on \mathbf{T} . The most extensively studied schema mappings are the ones in which Σ_{st} is a set of source-to-target tuple-generating dependencies (s-t tgds) and Σ_t is a weakly-acyclic set of target tuple-generating dependencies (target tgds) and target equality-generating dependencies (target egds) [11]. Note that tuple-generating dependencies are also known as GLAV (global-and-local as view) constraints; as special cases, they contain the classes of GAV (global-as-view) constraints and LAV (local-as-view) constraints. In [8], it was shown that computing the XR-Certain answers to target conjunctive queries is a coNP-complete problem in data complexity; in fact, this intractability persists even in the case in which Σ_{st} is a set of GAV constraints and Σ_t is a set of egds. Moreover, a connection with disjunctive logic programming was unveiled in [8] by showing that the XR-Certain answers of conjunctive queries can be rewritten as the cautious answers of a union of conjunctive queries with respect to the stable models of a disjunctive logic program over a suitably defined expansion of the source schema.

Here, our main aim is to explore how to effectively perform XR-Certain query answering for practical data exchange settings by leveraging modern sophisticated solvers for disjunctive logic programming. Disjunctive logic programming is a suitable formalism for coping with the intractability of XR-Certain query answering because it goes beyond the natural expressiveness of SQL while still remaining in a declarative framework. Our first technical result is a new improved reduction, accompanied by an optimized implementation, of the problem of computing the XR-Certain answers of queries in the context of data exchange to the problem of computing the certain answers of queries with respect to the stable models of disjunctive logic programs. We then evaluate this approach on a benchmark that we introduce here and which is modeled after a practical data exchange problem in computational genomics. Specifically, we present a benchmark scenario that mimics a portion of the data import process of the UCSC Genome Browser (<https://genome.ucsc.edu/>), a widely used genomics resource that “contains the reference sequence and working draft assemblies for a large collection of genomes.” We believe that data sets from computational sciences, such as computational genomics, are particularly in need of concepts and techniques that, like XR-Certain answers, eliminate the unquantifiable uncertainty that arise from constraint violations.

We carry out two experimental evaluations using real genomic data. The first is based on what we call a *monolithic* approach, which generates a disjunctive logic program from a given query and source instance, and then runs the *clingo* solver from the Potassco collection [12]. The results of this evaluation suggest that the solver fails to take advantage of some critical exploitable structural properties of the specific instances at hand. Intuitively, the cost of transforming the data from the source schema into the target schema is embedded in the execution cost of running each individual query, which causes large instances to become unworkable even for simple queries. In view of this, we develop a dif-

ferent *segmentary* approach that utilizes an improved encoding to take advantage of the aforementioned structural properties using techniques inspired by the notion of a *repair envelope*. The improved implementation utilizing these techniques computes query answers ten to one thousand times faster than the monolithic approach for large instances, and exhibits promising scalability with respect to the size of instances and the rate of target constraint violations.

2. PRELIMINARIES

This section contains definitions of basic notions and a minimum amount of background material on data exchange and on disjunctive logic programming. More detailed information about schema mappings and certain answers can be found in [1, 11].

Instances, Queries, and Homomorphisms. Fix an infinite set Const of elements, and an infinite set Nulls of elements such that Const and Nulls are disjoint. A *schema* \mathbf{R} is a finite set of relation symbols, each having a designated arity. An *\mathbf{R} -instance* is a finite database I over the schema \mathbf{R} whose active domain is a subset of $\text{Const} \cup \text{Nulls}$. A *fact* of an \mathbf{R} -instance I is an expression of the form $R(a_1, \dots, a_k)$, where R is a relation symbol of arity k in \mathbf{R} and (a_1, \dots, a_k) is a member of the relation R^I on I that interprets the symbol R . Every \mathbf{R} -instance can be identified with the set of its facts. We say that an \mathbf{R} -instance I' is a *sub-instance* of an \mathbf{R} -instance I if $I' \subseteq I$, where I' and I are viewed as sets of facts. If I is an \mathbf{R} -instance and $\mathbf{R}' \subseteq \mathbf{R}$, then by the *\mathbf{R}' -restriction* of I we will mean the subinstance of I containing only those facts that involve relations from \mathbf{R}' .

We assume familiarity with *conjunctive queries* (CQs) and *unions of conjunctive queries* (UCQs). The answers to a query q in an instance I are denoted by $q(I)$, and we denote by $q \downarrow(I)$ the answers of q on I that contain only values from Const .

The *active domain* of an instance I is the set of values from $\text{Const} \cup \text{Nulls}$ that occur in facts of I . By a *homomorphism* from an \mathbf{R} -instance I to another \mathbf{R} -instance I' , we mean a map h from the active domain of I to the active domain of I' , such that $h(c) = c$ for all $c \in \text{Const}$, and such that for every fact $R(v_1, \dots, v_n) \in I$ we have that $R(h(v_1), \dots, h(v_n)) \in I'$.

Schema Mappings. A *tuple-generating dependency* (tgd) over a schema \mathbf{R} is an expression of the form $\forall \mathbf{x}(\phi(\mathbf{x}) \rightarrow \exists \mathbf{y}\psi(\mathbf{x}, \mathbf{y}))$, where $\phi(\mathbf{x})$ and $\psi(\mathbf{x}, \mathbf{y})$ are conjunctions of atoms over \mathbf{R} . Tgds are also known as GLAV (global-and-local-as-view) constraints. Two important special cases are the GAV constraints and the LAV constraints. A GAV constraint is a tgd of the form $\forall \mathbf{x}(\phi(\mathbf{x}) \rightarrow P(\mathbf{x}))$ (that is, the right-hand side of the implication consists of a single atom without existential quantifiers) and a LAV constraint is a tgd of the form $\forall \mathbf{x}(R(\mathbf{x}) \rightarrow \exists \mathbf{y}\psi(\mathbf{x}, \mathbf{y}))$ (that is, the left-hand side of the implication consists of a single atom).

Let \mathbf{S} and \mathbf{T} be disjoint schemas, called the *source* schema and the *target* schema. A *source-to-target tgd* (s-t tgd, or, source-to-target GLAV constraint) is a tgd as defined above, where $\phi(\mathbf{x})$ is a conjunction of atoms over \mathbf{S} and $\psi(\mathbf{x}, \mathbf{y})$ is a conjunction of atoms over \mathbf{T} .

An *equality-generating dependency* (egd) over a schema \mathbf{R} is an expression of the form $\forall \mathbf{x}(\phi(\mathbf{x}) \rightarrow x_i = x_j)$ with $\phi(\mathbf{x})$ a conjunction of atoms over \mathbf{R} .

For the sake of readability, we will frequently drop universal quantifiers when writing tgds and egds.

A *schema mapping* is a quadruple $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$, where \mathbf{S} is a source schema, \mathbf{T} is a target schema, Σ_{st} is a finite set of s-t tgds, and Σ_t is a finite set of tgds and/or egds over the target schema. We will also call such schema mappings GLAV+(GLAV, EGD) schema mappings. In the special case where Σ_{st} consists of (source-to-target) GAV constraints and Σ_t consists of GAV constraints and/or egds, we will say that \mathcal{M} is a GAV+(GAV, EGD) schema mapping.

Universal Solutions and Certain Answers. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a schema mapping, and let I be a source instance. As usual in data exchange, we will assume that the source instances we consider do not contain null values.

A target instance J is a *solution* for a source instance I w.r.t. \mathcal{M} if the pair (I, J) satisfies the constraints of \mathcal{M} , that is, I and J together satisfy Σ_{st} , while J satisfies Σ_t . In general, a source instance may have many solutions. A *universal solution* for I (with respect to \mathcal{M}) is a solution J for I such that for all solutions J' of I , there is a homomorphism h from J to J' . Universal solutions are considered the preferred solutions in data exchange. One reason for this is that universal solutions can be used to compute certain answers to target queries.

If q is a query over the target schema \mathbf{T} , then the *certain answers* of q with respect to I and \mathcal{M} are defined as

$$\text{certain}(q, I, \mathcal{M}) = \bigcap \{q(J) : J \text{ is a solution for } I \text{ w.r.t. } \mathcal{M}\}$$

It was shown in [11] that, if J is a universal solution for a source instance I w.r.t. a schema mapping \mathcal{M} , then for every conjunctive query q , it holds that $\text{certain}(q, I, \mathcal{M}) = q \downarrow(J)$.

Weak Acyclicity and the Chase. If $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ is an arbitrary GLAV+(GLAV, EGD) schema mapping, then a given source instance may have no solution or it may have a solution, but no universal solution. For this reason, in [11] the concept of *weak acyclicity* was introduced, and it was shown that, when Σ_t is the union of a *weakly acyclic* set of target tgds and a set of egds, then, for all source instances I , a solution exists if and only if a universal solution exists. Moreover, the *chase procedure* can be used to determine in polynomial time (data complexity) whether a solution for I exists and, if so, to construct a universal solution for I in time polynomial in the size of I . The obtained solution, which we will denote by $\text{chase}(I, \mathcal{M})$ (when it exists), is known as the *canonical universal solution* of I . We refer to [11] for more details, including the definition of weak acyclicity and of the chase procedure.

By a GLAV+(WA-GLAV, EGD) schema mapping we will mean a schema mapping $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$, where Σ_{st} is a finite set of s-t tgds, and Σ_t is the union of a weakly acyclic set of target tgds and a set of egds. We spell out here two basic facts that are used in several arguments in this paper: let \mathcal{M} be any GLAV+WA-GLAV schema mapping (without egds). Then (i) every source instance I has a solution (and hence has a canonical universal solution), and (ii) whenever $I' \subseteq I$, then $\text{chase}(I', \mathcal{M}) \subseteq \text{chase}(I, \mathcal{M})$. The latter is also known as the *monotonicity of the chase*.

Disjunctive Logic Programming. A *disjunctive logic program* (DLP program) Π over a schema \mathbf{R} is a finite collection of rules of the form

$$\alpha_1 \vee \dots \vee \alpha_n \leftarrow \beta_1, \dots, \beta_m, \neg\gamma_1, \dots, \neg\gamma_k.$$

where $n, m, k \geq 0$ and $\alpha_1, \dots, \alpha_n, \beta_1, \dots, \beta_m, \gamma_1, \dots, \gamma_k$ are atoms formed from the relations in $\mathbf{R} \cup \{=, \neq\}$, using the constants in Const and first-order variables. A DLP program is said to be *ground* if it consists of rules that do not contain any first-order variables. A *model* of Π is an \mathbf{R} -instance I over the domain Const that satisfies all rules of Π (viewed as universally quantified first-order sentences). A *minimal model* of Π is a model M of Π such that there does not exist a model M' of Π where the facts of M' form a strict subset of the facts of M . For a ground DLP Π over a schema \mathbf{R} and an \mathbf{R} -instance M over the domain Const , the *reduct* Π^M of Π with respect to M is the DLP containing, for each rule $\alpha_1 \vee \dots \vee \alpha_n \leftarrow \beta_1, \dots, \beta_m, \neg\gamma_1, \dots, \neg\gamma_k$, with $M \not\models \gamma_i$ for all $i \leq k$, the rule $\alpha_1 \vee \dots \vee \alpha_n \leftarrow \beta_1, \dots, \beta_m$. A *stable model* of a ground DLP Π is an \mathbf{R} -instance M over the domain Const such that M is a minimal model of the reduct Π^M . See [13] for more details. The *cautious answers* to a query q , w.r.t. a DLP program Π (under the stable model semantics) are defined as

$$\bigcap \{q(s) \mid s \text{ is a stable model of } \Pi\}.$$

The stable model semantics is the most widely used semantics of DLP programs, and many solvers have been developed that support reasoning over stable models. In particular, stable models of disjunctive logic programs have been well-studied as a way to compute database repairs ([18] provides a thorough treatment).

3. EXCHANGE REPAIR FRAMEWORK

We briefly recall here the exchange-repair framework that was introduced in [8]. The development of this framework was motivated by the observation that the definition of $\text{certain}(q, I, \mathcal{M})$ trivializes when a source instance I has no solution w.r.t. a given schema mapping \mathcal{M} . XR-Certain answers were proposed as a semantics that provides meaningful answers to queries in such cases.

Definition 1. [8] Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a schema mapping, let I be an \mathbf{S} -instance.

1. A source instance I' is said to be a *source repair* of I with respect to \mathcal{M} if $I' \subseteq I$, I' has a solution with respect to \mathcal{M} , and no instance I'' with $I' \subsetneq I'' \subseteq I$ has a solution with respect to \mathcal{M} .
2. We say that a pair (I', J') is an *exchange-repair solution* (or XR-Solution) for I with respect to \mathcal{M} if I' is a source repair of I with respect to \mathcal{M} and J' is a solution for I' with respect to \mathcal{M} .
3. For a query q over the target schema \mathbf{T} , the *XR-certain answers* to q in I w.r.t. \mathcal{M} is the set

$$\text{XR-Certain}(q, I, \mathcal{M}) = \bigcap \{q(J') \mid (I', J') \text{ is an XR-Solution for } I \text{ w.r.t. } \mathcal{M}\}.$$

Note that, whenever a source instance I *does* have solutions w.r.t. \mathcal{M} , then, for all queries q , we have that

$\text{XR-Certain}(q, I, \mathcal{M}) = \text{certain}(q, I, \mathcal{M})$. While the XR-Certain semantics takes inspiration from the well-established notions of *database repairs* and *consistent query answers* [2, 4], the precise definition of the semantics reflects important assumptions that are specific to the context of data exchange. Specifically, the definitions of XR-Solution and XR-Certain reflect the fact that in a data exchange setting, it is preferred to make tgds satisfied by deriving additional facts, rather than by deleting facts; and the data used to answer target queries should derive from coherent sets of source facts.

It was shown in [8] that, in the case of $\text{GLAV}+(\text{WA-GLAV}, \text{EGD})$ schema mappings, the data complexity of XR-Certain query answering for conjunctive queries is coNP-complete (note that the restriction to weakly acyclic schema mappings is necessary here, since it follows from results in [11] that the same problem is undecidable for arbitrary $\text{GLAV}+(\text{GLAV}, \text{EGD})$ schema mappings). Furthermore, several approaches to query answering were studied in [8]. In particular, it was shown that, for $\text{GLAV}+(\text{WA-GLAV}, \text{EGD})$ schema mappings, XR-certain answers can be computed by means of a disjunctive logic program. We discuss this approach in the next section.

4. BASIC APPROACH TO QUERY ANSWERING

Based on the initial results in [8], we pursue here the development of a practical system for XR-Certain query answering via disjunctive logic programming, leveraging modern sophisticated solvers. Note that the emergence of such powerful solvers for NP-hard problems has already enabled practical solutions for many other computationally hard problems in industry. Concretely, in this section, we present a first implementation of XR-Certain query answering based on a translation along the lines of [8], that takes as input a schema mapping \mathcal{M} and a source instance I , and produces a single, typically large, DLP program whose stable models describe the XR-solutions of I w.r.t. \mathcal{M} . We refer to this as the *monolithic approach*, in order to contrast it with another approach, which will be presented in Section 6, involving multiple DLP programs of smaller size.

The first step in this approach consists of a reduction from the general case of $\text{GLAV}+(\text{WA-GLAV}, \text{EGD})$ schema mappings to the case of $\text{GAV}+(\text{GAV}, \text{EGD})$ schema mappings.

THEOREM 1 ([8]). *If $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ is a $\text{GLAV}+(\text{WA-GLAV}, \text{EGD})$ schema mapping and q a conjunctive query over \mathbf{T} , then there exist a $\text{GAV}+(\text{GAV}, \text{EGD})$ schema mapping $\hat{\mathcal{M}}$ and union of conjunctive queries \hat{q} such that $\text{XR-Certain}(q, I, \mathcal{M}) = \text{XR-Certain}(\hat{q}, I, \hat{\mathcal{M}})$.*

The resulting schema mapping may in general be exponentially larger than the original. However, as we will see in Section 5.2, our implementation incurs only a modest increase when applied to our benchmark.

Next, in [8], we present a very natural and concise encoding of XR-Certain for $\text{GAV}+(\text{GAV}, \text{EGD})$ schema mappings as the cautious answers over the parallel circumscription of a disjunctive logic program Π . In [15] it was shown that the problem of finding such models can be subsequently reduced to that of computing stable models of a translation of Π into a new disjunctive logic program. However, the translation involved requires the explicit representation of the herbrand

base of the source instance, which can be prohibitively large even for small source instances. We now present an improved, direct reduction of XR-Certain to the cautious answers over stable models of a disjunctive logic program.

In order to facilitate the discussion below, it is convenient to introduce the notion of a *canonical* XR-Solution. An XR-Solution (I', J') for I w.r.t. \mathcal{M} is said to be a *canonical* XR-Solution if J' is a canonical universal solution for I' w.r.t. \mathcal{M} , that is, $J' = \text{chase}(I', \mathcal{M})$.

For any $\text{GAV}+(\text{GAV}, \text{EGD})$ schema mapping $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$, let $\Pi_{\mathcal{M}}$ be the DLP program given in Figure 1. Observe that the schema of the program $\Pi_{\mathcal{M}}$ contains multiple distinct copies of each relation from $\mathbf{S} \cup \mathbf{T}$. The program in Theorem 2 intends to describe the canonical XR-Solutions of a source instance. Suppose (I', J') is a canonical XR-Solution for some source instance I w.r.t. a $\text{GAV}+(\text{GAV}, \text{EGD})$ schema mapping $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$, and let J be the canonical universal solution for I w.r.t. the tgds of \mathcal{M} . The program introduces three predicates for each source relation, one with the original name meant to contain the facts of I , one subscripted with **d** (“deleted”) meant to contain the facts of $I \setminus I'$, and one subscripted with **r** (“remains”) meant to contain the facts of I' . The program also introduces these same three predicates for each target relation, plus a fourth subscripted with **i** (“incidentally deleted”) meant to contain the target facts in $J \setminus J'$ that are also contained in some subset $J'' \supseteq J'$ of J that is consistent with Σ_t (that is, they are not in a canonical XR-Solution but they may appear in some other XR-Solution).

For every stable model M of $\Pi_{\mathcal{M}}$, we denote by I^M and J^M the \mathbf{S} -instance and \mathbf{T} -instance consisting of those facts $R(\mathbf{a})$ in the relevant schema for which $R_r(\mathbf{a}) \in M$.

THEOREM 2. *Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a $\text{GAV}+(\text{GAV}, \text{EGD})$ schema mapping and I a source instance. The XR-solutions of I w.r.t. \mathcal{M} are precisely those pairs of instances that are of the form (I^M, J^M) for some stable model M of $\Pi_{\mathcal{M}} \cup I$.*

COROLLARY 1. *Let \mathcal{M} be a $\text{GAV}+(\text{GAV}, \text{EGD})$ schema mapping. For every union of conjunctive queries q and for every source instance I ,*

$$\text{XR-Certain}(q, I, \mathcal{M}) = \bigcap \{q_r(s) \mid s \text{ a stable model of } \Pi_{\mathcal{M}} \cup I\}$$

where q_r is the query formed from q by replacing every occurrence of a relation R with R_r .

With this new encoding, we can now compute XR-Certain using the disjunctive logic program $\Pi_{\mathcal{M}} \cup I$, whose size is linear in the combined size of the source instance and schema mapping. The DLP generated using the prior approach of [8], in contrast, is lower-bounded in size by $|\text{adom}(I)|^s$, where s is the maximum arity of the relations in the source schema.

5. SCENARIO: GENOME BROWSER

Scientific data is a potentially important application of XR-Certain query answering because research decisions and discoveries are often made based on data drawn from a variety of sources, and because unquantifiable uncertainty must

For each tgd $(R1(\mathbf{x}, \mathbf{y}) \wedge \dots \wedge Rn(\mathbf{x}, \mathbf{y}) \rightarrow T(\mathbf{x})) \in (\Sigma_{st} \cup \Sigma_t)$, construct a *chase rule*, *deletion rule*, and *target remainder rule* respectively:

$$\begin{aligned} T(\mathbf{x}) &\leftarrow R1(\mathbf{x}, \mathbf{y}), \dots, Rn(\mathbf{x}, \mathbf{y}). \\ R1_d(\mathbf{x}, \mathbf{y}) \vee \dots \vee Rn_d(\mathbf{x}, \mathbf{y}) &\leftarrow T_d(\mathbf{x}), R1(\mathbf{x}, \mathbf{y}), \dots, Rn(\mathbf{x}, \mathbf{y}), \\ &\quad \neg R1_i(\mathbf{x}, \mathbf{y}), \dots, \neg Rn_i(\mathbf{x}, \mathbf{y}). \\ T_r(\mathbf{x}) &\leftarrow R1_r(\mathbf{x}, \mathbf{y}), \dots, Rn_r(\mathbf{x}, \mathbf{y}). \end{aligned}$$

For each egd $(R1(\mathbf{x}) \wedge \dots \wedge Rn(\mathbf{x}) \rightarrow x_i = x_j) \in \Sigma_t$, construct a *deletion rule*:

$$R1_d(\mathbf{x}) \vee \dots \vee Rn_d(\mathbf{x}) \leftarrow R1(\mathbf{x}), \dots, Rn(\mathbf{x}), x_i \neq x_j, \neg R1_i(\mathbf{x}), \dots, \neg Rn_i(\mathbf{x}).$$

For each relation $R \in \mathbf{S}$, construct a *source remainder rule*:

$$R_r(\mathbf{x}) \leftarrow R(\mathbf{x}), \neg R_d(\mathbf{x})$$

For each relation $R \in \mathbf{T}$, construct an *incidental deletion rule*, and the *one-of-three rules*:

$$\begin{aligned} R_i(\mathbf{x}) &\leftarrow R(\mathbf{x}), \neg R_r(\mathbf{x}), \neg R_d(\mathbf{x}) \\ \perp &\leftarrow R_r(\mathbf{x}), R_d(\mathbf{x}) \\ \perp &\leftarrow R_r(\mathbf{x}), R_i(\mathbf{x}) \\ \perp &\leftarrow R_d(\mathbf{x}), R_i(\mathbf{x}) \end{aligned}$$

Figure 1: Procedure to construct the disjunctive logic program $\Pi_{\mathcal{M}}$

be eliminated from the data before a decision or discovery is made. The guarantee given by XR-Certain query answers – that all possible repairs of the source instance agree on them – is a natural fit for these circumstances.

Inspired by the UCSC Genome Browser, we present a benchmark that uses real data: a loose simulation of the genome browser data import process. The UCSC Genome Browser database is constructed using a variety of algorithms and public data sources. Our benchmark focuses on the human gene model, a set of genomic sequences which putatively capture the portion of the human genome that encodes proteins. The UCSC Genome Browser algorithms compute these sequences from a reference genome by computing alignments for known/observed proteins and transcripts from the UniProt and GenBank databases [14]. For our purposes, we treat the set of transcripts as given (that is, as a source instance rather than the result of a computation), and we provide a schema mapping mimicking how this data, plus a significant volume of data from the RefSeq, Entrez Gene, and UniProt databases, are combined and transformed into the UCSC Genome Browser database. Our schema mapping makes several loose approximations of scientific reality which serve to maximize the portion of the genome browser schema that we populate, but which also introduce some inconsistency to the data. It is for this reason that we say our schema mapping merely *mimicks* the true UCSC Genome Browser data import process, even though our target schema is faithful to the real database.

The RefSeq and EntrezGene databases are not available for download in a flat relational format. The RefSeq database is offered in a text file format, within which the data are arranged in a nested fashion with transcripts as the top-level elements. Every transcript has associated source and reference information (documenting how and by whom

Table 1: Source Instances

Database	Relations	total # of Attributes	total # of Tuples
UCSC*	2	13	165,920
RefSeq	5	38	706,923
EntrezGene	1	3	431,114
UniProt	1	3	4,405,573

*Transcript alignments and crossreference only.

it was observed), and each may have subsections specifying what protein it encodes and what gene it is transcribed from. These subsections often link to other databases using external protein and gene identifiers. Our ETL step places transcripts, sources, references, genes, and proteins into five separate respective relations, all keyed by transcript accession identifier. The EntrezGene database is available in ASN.1 format, which we first convert to xml using the `gene2xml` tool from the NCBI ToolBox [19]. From the resulting xml, we extract the desired fields into a single table using the `xtract` tool from NCBI Entrez Direct [20].

Our complete schema mapping is available for download at <https://users.soe.ucsc.edu/~rhalpert/xr-benchmarks/>. Table 1 summarizes the data sources.

We represent the given part of UCSC’s gene model with two tables, `ComputedAlignments`, which holds data about the transcripts themselves, and `ComputedCrossref`, which holds a cross-reference between UCSC “known gene IDs” (referred to here as “transcripts”) and the closest corresponding external database transcript identifier (usually a RefSeq accession) and protein identifier (usually a UniProt or RefSeq accession). Our hand-written schema mapping specifies how these tables and the RefSeq, EntrezGene, and UniProt databases are used to populate the target schema. It also applies a key constraint to each target relation, per industry best-practice. Many of the key constraints are specified by the Genome Browser’s schema, while some are not specified but are reasonable constraints that are in fact satisfied by the Genome Browser data.

The true Genome Browser’s process computes a single coherent truth which may differ from that represented in the external databases. Our schema mapping, on the other hand, consolidates these sources into the target schema, and this gives rise to some inconsistency. The key constraints on the `knownGene` and `kgXref` tables prove critical in this regard: they enforce that each transcript have exactly one value for the exon count, and one gene symbol, respectively. Since values from both the UCSC gene model and from the other sources are used to populate the relevant attributes, this effectively gives rise to constraint violations when the UCSC gene model disagrees with RefSeq on the number of exons, and when RefSeq and EntrezGene collectively list more than one gene symbol. These two circumstances are expected to arise a small fraction of the time. The relevant parts of the schema mapping are depicted in Figure 2.

The `knownIsoforms` relation groups transcripts into clusters, where each cluster represents a gene. The Genome Browser computes this relation based on genomic coordinates [14]. Our schema mapping populates the `knownIsoforms` relation using a naive simplification of this approach: transcripts that share either an Entrez Gene ID or a gene symbol are made to reside in the same cluster. These two

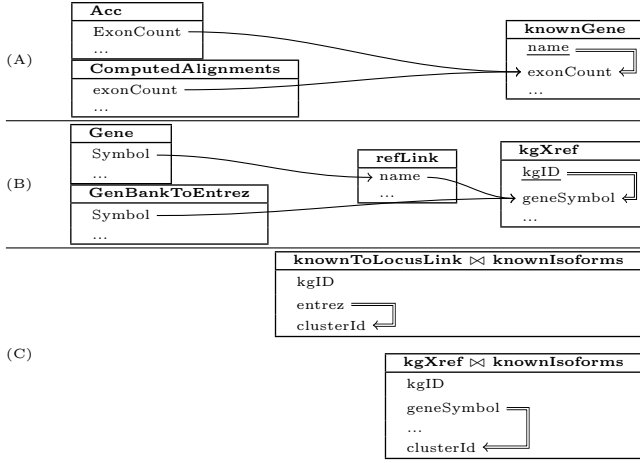

Figure 2: Critical parts of the schema mapping. Single arrows represent value propagation via tgds, and double arrows represent functional dependencies (egds). Keys (also egds) are underlined. (A) Competing values for the exon count. (B) Competing values for the gene symbol. (C) Clustering of transcripts according to Entrez Gene ID and gene symbol. The indicated egds give rise to equalities between nulls.

approaches are incomparable. Ours relies on existing gene symbol annotations from Entrez and UniProt, as well as crossreference annotations on UCSC transcripts, all of which have different levels of rigor and completeness. The known-Isoforms table is thus included in our schema mapping primarily to exercise the interaction of existentially quantified values with egds, which is a differentiating feature of weakly acyclic schema mappings versus other types of syntactic restrictions of GLAV+(GLAV, EGD) schema mappings (e.g., GAV+(GAV, EGD) or separable [6] schema mappings). This part of the schema mapping is depicted in Figure 2.

5.1 Benchmark Data and Queries

We wish to test the scalability of our implementation relative to two factors: the instance size and the proportion of the source tuples “involved” in egd violations (called “suspect” tuples), which we make precise with the notion of a *source repair envelope* defined in Section 6.2). To this end, we define a set of instances having specified sizes and ratios of suspect to total source tuples. In order to construct our test instances, we chase the unmodified source instances with the schema mapping and compute which source tuples are suspect. We call this the *raw result*. Then, each test instance is produced by selecting a randomized subset of the source instances with the desired size and ratio of suspect to total tuples in one particular table (ComputedCrossref), which we use as a rough proxy for the ratio for the entire source. Thus, for the largest size (“full”), the maximum ratio is the ratio found in the raw result (2.9%), and there is only one such instance. For the smaller instances, we are able to select enough suspect tuples to produce larger ratios. We use a randomized selection procedure to materialize a set of instances for each profile; six (at 3% suspect) for small and medium instances, three per ratio for large instances, and, necessarily, just one full instance (at 2.9% suspect). The characteristics of these instances are given in Table 2.

Table 2: Test instances have sizes small (S), medium (M), large (L), and full (F), and 0, 3, 9, or 20 percent of their transcripts suspect.

instance:	L0	L3	L9	L20
source tuples	321k	322k	316k	301k
total tuples	716k	724k	731k	748k
suspect transcripts	0%	3%	9%	20%
suspect tuples*	0%	2.0%	5.8%	13.4%

instance:	S3	M3	L3	F3
source tuples	3.5k	36k	322k	1,846k
total tuples	7.9k	77k	724k	5,354k
suspect transcripts	3%	3%	3%	2.9%
suspect tuples*	1.8%	1.8%	2.0%	3.4%

*includes source and target

Table 3 lists our query suite. Queries labeled “epN” are adapted from the EQUIP query suite [16]: five of the 21 queries given there are applicable to our target schema. Additional queries labeled “xrN” are new queries created to exercise the critical parts of the schema mapping, including what is XR-Certain knowledge in the knownGene relation, and what pairs of transcripts reside in the same cluster in the knownIsoforms relation. In our experiments, we run the queries sequentially.

5.2 Monolithic Implementation and Results

Using the reduction given in Theorem 2, we have implemented a *monolithic* approach to XR-Certain query answering. Our monolithic implementation takes as input a GLAV+ (WA-GLAV, EGD) schema mapping (encoded as text), an arbitrary source instance (via a JDBC connection string), and a union of conjunctive queries over the target schema (also text). The schema mapping is transformed into a GAV+(GAV, EGD) schema mapping using an optimized version of the reduction in Theorem 1, and the query is transformed into a new union of conjunctive queries using the same reduction. These transformations take an average of 18.7 seconds combined, and the resulting schema mapping is approximately seven times larger than the original (from 33 tgds and 26 egds to 339 tgds and 67 egds). We generate a separate disjunctive logic program for each query and instance, and run them using clingo 4.4.0, a solver from the Potsdam Answer Set Solving Collection[12] (Potassco).

All experiments are run on an 8-core Intel Core i7-2720QM CPU @2.20GHz with 16GB RAM, running Ubuntu 14.04 LTS (Linux 3.13.0 SMP x86_64). The plots of Figure 3 depict the runtime for these programs versus the percentage of suspect tuples and versus the instance size, respectively, with a line for each query. The latter is a log-log plot, since each instance size is an order of magnitude larger than the last.

These results illustrate a significant problem with this *monolithic* logic program approach: the cost of transforming the data from the source schema into the target schema is embedded in the execution cost of each individual query, which causes large instances to become unworkable even for simple queries. Additionally, the rapid increase in query runtimes as instance size increases, even for queries whose answers should be easy to compute, suggest that this implementation fails to take advantage of some exploitable structure in the instance and schema mapping. This is perhaps a symptom of the fact that the disjunctive logic program’s rules are no simpler for areas of the source and target in-

Table 3: Query Suite, with approximate answer counts for the large-size instances.

Query	Answers
ep1() :- refLink(symbol, _, acc, protacc, _, _, _, _), kgXref(ucscid, _, spid, _, symbol, _, _, _, _)	1*
ep2(protacc) :- refLink(symbol, _, acc, protacc, _, _, _, _), kgXref(ucscid, _, spid, _, symbol, _, _, _, _)	6,000
ep3(protacc,spid) :- refLink(symbol, _, acc, protacc, _, _, _, _), kgXref(ucscid, _, spid, _, symbol, _, _, _, _)	12,000
ep15(symbol) :- kgXref(ucscid, _, _, _, symbol, refseq, _, _, _, _), refLink(_, product, refseq, _, _, _, entrez, _)	1,500
ep16(symbol,entrez) :- kgXref(ucscid, _, _, _, symbol, refseq, _, _, _, _), refLink(_, product, refseq, _, _, _, entrez, _)	1,500
xr1() :- knownGene(kgid, ch, sd, txs, txe, cs, ce, exc, exs, exe, pac, alignid)	1*
xr2(kgid) :- knownGene(kgid, ch, sd, txs, txe, cs, ce, exc, exs, exe, pac, alignid)	10,000
xr3(kgid, ch, sd, txs, txe, cs, ce, exc, exs, exe, pac, ai) :- knownGene(kgid, ch, sd, txs, txe, cs, ce, exc, exs, exe, pac, ai)	10,000**
xr4() :- knownIsoforms(cluster, transcript1), knownIsoforms(cluster, transcript2)	1*
xr5(transcript1) :- knownIsoforms(cluster, transcript1), knownIsoforms(cluster, transcript2)	10,000
xr6(transcript1, transcript2) :- knownIsoforms(cluster, transcript1), knownIsoforms(cluster, transcript2)	35,000

stances that are unaffected by egd violations than for those that are affected. In the following section, we will develop techniques to identify and exploit such structure by grounding the egds.

6. ENHANCED APPROACH TO QUERY ANSWERING

Although the monolithic approach serves as a precise, straightforward specification of XR-Certain answers, it does not lend itself to fine-grained optimization. In this section, we present practical adaptations and optimizations to XR-Certain query answering that are motivated by our experimentation with the monolithic implementation, and that draw on techniques described in the literature for query answering over inconsistent databases, specifically, the notion of *repair envelopes* introduced by Eiter *et al.* [10]. We split query answering into two phases. The first, the “exchange phase”, is a tractable-time query-independent preprocessing step, which enables the second, the “query phase”, in which XR-Certain answers to a particular query are computed by solving a collection of small disjunctive logic programs. Although the problem at hand is coNP-complete, this new *segmentary approach* allows us to answer queries by solving many small hard problems rather than one large one. At the end of this section, we evaluate an implementation based on this enhanced approach.

6.1 Candidate Answers

The following definition of *candidate answers* effectively

provides an upper bound on the set of XR-Certain answers of a query, in the sense that the latter is always a subset of the former.

Definition 2. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping.

1. We denote by \mathcal{M}^{tgd} the schema mapping $(\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t^{tgd})$ where Σ_t^{tgd} consists of the tgds from Σ_t . That is, all egds are dropped.
2. The *canonical quasi-solution* of a source instance I w.r.t. \mathcal{M} is the canonical universal solution of I w.r.t. \mathcal{M}^{tgd} .
3. For every UCQ q over \mathbf{T} , the *candidate answers* to q w.r.t. I and \mathcal{M} are $q(J)$, where J is the canonical quasi-solution of I w.r.t. \mathcal{M} .

PROPOSITION 1. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping. Let I be an \mathbf{S} -instance. Let J be the canonical quasi-solution of I w.r.t. \mathcal{M} .

1. For all canonical XR-Solutions (I', J') for I w.r.t. \mathcal{M} , it holds that $J' \subseteq J$.
2. For every UCQ q , we have that $\text{XR-Certain}(q, I, \mathcal{M}) \subseteq q(J)$. That is, every XR-Certain answer is indeed a candidate answer.

PROOF. Let (I', J') be a canonical XR-Solution for I w.r.t. \mathcal{M} . Since \mathcal{M} is GAV+(GAV, EGD) and J' is the canonical universal solution for I' w.r.t. \mathcal{M} , J' is simply the closure

of I' w.r.t. the tgds of \mathcal{M} . Therefore J' is also the canonical universal solution for I' w.r.t. \mathcal{M}^{tgd} . Finally, since the chase procedure is monotone [11] and $I' \subseteq I$, we have that $J' \subseteq J$.

The second item follows directly from the first, since UCQs are monotone queries. \square

6.2 Source Repair Envelopes

It is often possible to exclude a large portion of the database from high-complexity computations. We will define a notion similar to a *repair envelope* from [10] but suited to the setting of data exchange.

Definition 3. Let \mathcal{M} be a GLAV+(WA-GLAV, EGD) schema mapping and I a source instance. A subset E of I is a *source repair envelope* if $(I \setminus I') \subseteq E$ for all source repairs I' .

We will now see that we can restrict our attention within a source repair envelope when computing source repairs.

PROPOSITION 2. Let \mathcal{M} be a GLAV+(WA-GLAV, EGD) schema mapping, I a source instance, and $E \subseteq I$ a source repair envelope for I w.r.t. \mathcal{M} . Then $\{I' \mid I' \text{ is a source repair of } I \text{ w.r.t. } \mathcal{M}\} = \{E' \cup (I \setminus E) \mid E' \text{ is a source repair of } E \text{ w.r.t. } \mathcal{M}\}$.

PROOF. Claim: $I' \cap E$ is a source repair of E .

Suppose for the sake of contradiction that $I' \cap E$ is not a source repair of E . Then either $I' \cap E$ has no solution (which cannot be the case due to monotonicity of the chase) or $I' \cap E$ is strictly contained in a source repair E'' of E . But then E'' must be contained in a source repair I'' of I . However, the definition of a source repair envelope tells us that I'' contains all of $E'' \cup (I \setminus E)$. Hence it contains I' , so I' wasn't a source repair of I after all.

Claim: if E' is a source repair of E then $E' \cup (I \setminus E)$ is a source repair of I .

Indeed, E' must be contained in a source repair of I , and by the definition of a source repair envelope, that source repair of I must contain all of $(I \setminus E)$. Therefore it contains $E' \cup (I \setminus E)$. However, it cannot be a strict superset of $E' \cup (I \setminus E)$ because then E' could be extended to a larger source repair of E . \square

There are many ways to calculate a source repair envelope (e.g., I is a trivial source repair envelope). Consider the *ideal source repair envelope*, given by $I - \bigcap \{I' \mid I' \text{ is a source repair for } I \text{ w.r.t. } \mathcal{M}\}$. Equivalently, the ideal source repair envelope is the minimal source repair envelope for I w.r.t. \mathcal{M} . The next result tells us that computing this envelope is hard.

THEOREM 3. Fix a schema mapping \mathcal{M} . Let the intersection of source repairs membership problem be the following decision problem: given a source instance I , and a fact f of I , is f contained in the intersection of all source repairs (that is, is $f \in \bigcap \{I' \mid I' \text{ is a source repair for } I \text{ w.r.t. } \mathcal{M}\}$)? There is a GAV+(GAV, EGD) schema mapping for which this problem is coNP-hard.

PROOF. The result is proven by reduction from the complement of 3-colorability. Let $G = (V, E)$ be a graph, with edge set $E = \{e_1, \dots, e_n\}$. I_G is the source instance, with active domain $V \cup \{1, \dots, n\}$, containing, for each edge $e_i = (a, b)$ the fact $E(a, b, i, i+1)$; for each vertex $a \in V$, the

facts $C_r(a), C_g(a), C_b(a)$; and one additional fact, namely $F(n, 1)$.

\mathcal{M} is the schema mapping consisting of the source-to-target tgds

- $E(x, y, u, v) \wedge C_z(x) \rightarrow E'(x, y)$ (for $z \in \{r, g, b\}$)
- $E(x, y, u, v) \wedge C_z(x) \rightarrow F'(u, v)$ (for $z \in \{r, g, b\}$)
- $P_z(x) \rightarrow P'_z(x)$ (for $z \in \{r, g, b\}$)
- $F(u, v) \rightarrow F'(u, v)$

and target constraints

- $E'(x, y) \wedge P'_z(x) \wedge P'_z(y) \wedge F'(u, v) \rightarrow u = v$ (for all $z \in \{r, g, b\}$)
- $F'(u, v) \wedge F'(v, w) \rightarrow F'(u, w)$
- $F'(u, u) \wedge F'(v, w) \rightarrow v = w$

Note that I has no solutions with respect to \mathcal{M} , regardless of whether G is 3-colorable. This is because a solution J of I has to contain a directed cycle of F' -edges (of length n), and F' must be transitive, which means that J would have to include facts of the form $F'(i, i)$, leading to an egd violation. Indeed, every source-repair of I must either (i) omit at least one of the E -facts, or (ii) omit all P_z -facts ($z \in \{r, g, b\}$) for some vertex or (iii) omit the $F(n, 1)$ fact. It is then not hard to see that G is 3-colorable if and only if some source repair omits $F(n, 1)$. Note that, if G is 3-colorable, then there is a source repair that retains all E -facts and that retains at least one P_z -fact for each vertex ($z \in \{r, g, b\}$). This source repair must then omit the $F(n, 1)$ fact. If, on the other hand, G is not 3-colorable, then every source repair has to satisfy (i) or (iii) and, consequently, will include $F(n, 1)$. \square

The hardness established in Theorem 3 shows that computing the ideal source repair envelope is not helpful, given that the purpose of a source repair envelope is to help reduce the need for high-complexity computations. Our next result pertains to a source repair envelope that *can* be computed in PTIME.

First, we introduce the notion of *support sets* for a target fact. For an egd or GAV tgd σ and an instance I , we denote by $\text{ground}(\sigma, J)$ the set of all groundings of σ using values from the active domain of I (that is, quantifier-free formulas that can be obtained from σ by replacing universally quantified variables by values from the active domain of I). Note that, if J is a canonical quasi-solution for a source instance I w.r.t. a GAV+(GAV, EGD) schema mapping, then the active domain of J is already included in the active domain of I .

Definition 4. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{\text{st}}, \Sigma_{\text{t}})$ be a GAV+(GAV, EGD) schema mapping. Let I be an \mathbf{S} -instance with canonical quasi-solution J , and let $f \in J$ be a fact.

- A *support set* for f is a set of the form $\{f_1, \dots, f_n\}$ where $(f_1 \wedge \dots \wedge f_n \rightarrow f) \in \text{ground}(\Sigma_{\text{st}} \cup \Sigma_{\text{t}}, I)$, and $(I, J) \models f_1 \wedge \dots \wedge f_n$. The set of all support sets of f is denoted by $\text{support_sets}(f, I, \mathcal{M})$.
- The *support closure* for a set F of facts, denoted as $\text{support}^*(F, I, \mathcal{M})$, is the smallest set containing F such that whenever $g \in \text{support}^*(F, I, \mathcal{M})$, then all facts that belong to a support set of g belong to $\text{support}^*(F, I, \mathcal{M})$ as well.

Definition 5. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{\text{st}}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping. Let J be the canonical quasi-solution of I . Let

$$\text{violations}(I, \mathcal{M}) = \left\{ f \mid \begin{array}{l} f \text{ occurs in the body of some} \\ \sigma \in \text{ground}(\Sigma_t, I) \text{ with } J \not\models \sigma \end{array} \right\}$$

We say that a source fact $f \in I$ is *suspect* (w.r.t. \mathcal{M}) if it belongs to $\text{support}^*(\text{violations}(I, \mathcal{M}), I, \mathcal{M})$, and that it is *safe* otherwise. The set of suspect facts of I is denoted by I_{suspect} and the set of safe facts of I is denoted by I_{safe} .

The violation set is, intuitively, the set of facts that are directly involved in an egd violation, while the violation closure is, intuitively, the set of facts that are, possibly indirectly, involved in an egd violation. The notation I_{safe} and I_{suspect} assumes that it is clear from the context which schema mapping is being referred to.

PROPOSITION 3. Let \mathcal{M} be a GAV+(GAV, EGD) schema mapping and I a source instance. Then I_{suspect} is a source repair envelope for I (w.r.t. \mathcal{M}). Moreover, I_{suspect} can be computed in polynomial time (data complexity).

To see that this proposition holds, suppose that some $f \in I$ is omitted by a source repair I' of I . Then $I' \cup \{f\}$ has no solution. It follows that f must be in the violation closure of I w.r.t. \mathcal{M} (with the steps of the chase of $I' \cup \{f\}$ serving as proof of such). Therefore, f belongs to I_{suspect} .

The following example reminds us that I_{suspect} is not necessarily a *minimal* source repair envelope.

Example 1. Let $I = \{P(a, b), P(a, c), Q(b, c)\}$, and let $\mathcal{M} = (\{P, Q\}, \{P', Q'\}, \{P(x, y) \rightarrow P'(x, y), Q(x, y) \rightarrow Q'(x, y)\}, \{P'(x, y) \wedge P'(x, y') \rightarrow y = y', P'(x, y) \wedge P'(x, y') \wedge Q'(y, y') \rightarrow y = y'\})$. Then

$$I_{\text{suspect}} = \{P(a, b), P(a, c), Q(b, c)\}$$

However, the key constraint on P' forces every XR-Solution to have at most one of $P(a, b), P(a, c)$, so the second egd in Σ_t is satisfied without eliminating $Q(b, c)$. Indeed, the ideal source repair envelope for I is $\{P(a, b), P(a, c)\}$.

Nonetheless, I_{suspect} is a potentially useful source repair envelope: we vary the proportion of facts in I_{suspect} versus I_{safe} in our test instances in order to evaluate the importance of this measure.

We will now extend the notion of a source repair envelope to include target instances.

Definition 6. Let \mathcal{M} be a GAV+(GAV, EGD) schema mapping, and I a source instance. Let J be the canonical quasi-solution of I . Two sets $E \subseteq I$ and $F \subseteq J$ of facts, together comprise an *exchange repair envelope* (E, F) if, for all canonical XR-Solutions (I', J') of I w.r.t. \mathcal{M} , we have that $(I \setminus I') \subseteq E$ and $(J \setminus J') \subseteq F$.

It follows from Theorem 3 that computing the minimal exchange repair envelope is hard. We will now see how to extend an existing source repair envelope to the target, in polynomial time.

Definition 7. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{\text{st}}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping, and I be an \mathbf{S} -instance. Let J be the canonical quasi-solution of I w.r.t. \mathcal{M} . Define the *influence* of a set of facts $E \subseteq I$, denoted $\text{influence}(E, I, \mathcal{M})$,

as the smallest set containing E such that whenever $g \in \text{influence}(E, I, \mathcal{M})$, every fact f that has a support set containing g also belongs to $\text{influence}(E, I, \mathcal{M})$.

PROPOSITION 4. Let \mathcal{M} be a GAV+(GAV, EGD) schema mapping and I a source instance. Let J be the canonical quasi-solution of I w.r.t. \mathcal{M} . Let E be a source repair envelope for I w.r.t. \mathcal{M} , and let $F = \text{influence}(E, I, \mathcal{M})$. Then (E, F) is an exchange repair envelope for I w.r.t. \mathcal{M} .

In particular, $(I_{\text{suspect}}, J_{\text{suspect}})$ is an exchange repair envelope for I , where $J_{\text{suspect}} = \text{influence}(I_{\text{suspect}}, I, \mathcal{M})$.

PROOF. Let (I', J') be a canonical XR-Solution for I w.r.t. \mathcal{M} . Let t be a fact in $J \setminus J'$. Since t is not in (I', J') , there must be some fact f in $\text{support}^*(\{t\}, I, \mathcal{M})$ in $I \setminus I'$. Therefore, f is contained in the source repair envelope E , so by definition we have that $t \in \text{influence}(E, I, \mathcal{M})$. \square

Fact 1. The following two statements hold, where F is an arbitrary set of target facts:

- The influence of the source restriction of the support closure of F contains the support closure of F ; and
- A support closure of F and its influence are equal over their source restrictions.

In light of the above, we can refer to violation influences instead of violation closures whenever we wish to work with exchange repair envelopes rather than source repair envelopes. It is important to notice that a fact may have one support set which places it in a violation influence, but also another support set whose facts are not contained in any violation influence. Such facts lie in the difference between the violation influence and the ideal exchange repair envelope, but are nonetheless easy to identify.

6.3 Violation Clusters

Violation clusters are a concept that will help us further reduce the combinatorial complexity of computing XR-Certain answers. We start with a motivating example.

Example 2. Let $I = \{P_1(a, b), P_1(a, c), P_2(a, b), P_2(a, c), \dots, P_n(a, b), P_n(a, c)\}$, and let

$$\begin{aligned} \mathcal{M} = (\{P_1, \dots, P_n\}, \{Q_1, \dots, Q_n\}, \\ \{P_1(x, y) \rightarrow Q_1(x, y), \dots, P_n(x, y) \rightarrow Q_n(x, y)\}, \\ \{Q_1(x, y) \wedge Q_1(x, y') \rightarrow y = y', \dots, \\ Q_n(x, y) \wedge Q_n(x, y') \rightarrow y = y'\}) \end{aligned}$$

There are 2^n source repairs, which can be built by choosing one source atom from each of the n relations, in every possible combination. In this sense, the set of source repairs for this example is highly structured.

Now consider the query $q(x) :- Q_1(x, y)$. Every source repair of I w.r.t. \mathcal{M} contains either $P_1(a, b)$ or $P_1(a, c)$, so we can conclude that $q(a) \in \text{XR-Certain}(q, I, \mathcal{M})$ by considering just the two possibilities for the P_1 relation. In so doing, we ignore the other $n - 1$ relations and avoid having to consider 2^n source repairs.

In this section, we will generalize the above observation and demonstrate that it can be used to reduce the size of instances and schema mappings for which we must explore

all source repairs. To do so, we introduce a notion of *independence* that captures when particular egd violations are sufficiently isolated from each other to be processed separately.

To simplify the presentation, it will be convenient to consider schema mappings $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ in which Σ_t may contain *grounded egds* (where universally quantified variables have been replaced by constants). This will allow us to more easily describe how an instance is carved up into segments that can be processed independently. Intuitively, each grounding of an egd describes one potential violation of that egd. The notions of solutions, universal solutions, source repairs, and exchange repair solutions all apply without modification to schema mappings containing grounded egds.

As a slight abuse of notation, when D is a set of target constraints, we will write $\mathcal{M} \cup D$ to denote the schema mapping obtained by adding the constraints in D to the target constraint set of a schema mapping \mathcal{M} .

Definition 8. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping. Let I be an \mathbf{S} -instance. Let J be the canonical quasi-solution for I w.r.t. \mathcal{M} . Let $\sigma_1, \sigma_2 \in \text{ground}(\Sigma_t, I)$ be distinct grounded egds with $J \not\models \sigma_1$ and $J \not\models \sigma_2$. Let E_1 be the ideal source repair envelope for I w.r.t. $(\mathcal{M}^{tgd} \cup \{\sigma_1\})$, and let E_2 be the ideal source repair envelope for I w.r.t. $(\mathcal{M}^{tgd} \cup \{\sigma_2\})$. We say σ_1 and σ_2 are *pairwise-independent* if $\text{source_repairs}(I, \mathcal{M}^{tgd} \cup \{\sigma_1, \sigma_2\}) = \{(I \setminus (E_1 \cup E_2)) \cup E'_1 \cup E'_2 \mid E'_1 \in \text{source_repairs}(I \cap E_1, \mathcal{M}^{tgd} \cup \{\sigma_1\}) \text{ and } E'_2 \in \text{source_repairs}(I \cap E_2, \mathcal{M}^{tgd} \cup \{\sigma_2\})\}$. We say σ_1 and σ_2 are *pairwise-dependent* if they are not *pairwise-independent*.

Consider the graph of all egd violations in the quasi-solution and connect each pair of pairwise dependent egd violations by an edge. Each connected component of this graph is called a *violation cluster*. If σ_1 and σ_n reside in distinct violation clusters then we say σ_1 and σ_n are *independent*.

If a pair of violations is independent, by definition, their XR-Solutions can be processed separately, then suitably recombined. Note that the above definition of violation clusters does not provide us with a way to compute them efficiently, because the definition involves ideal source repair envelopes. The following proposition provides an approximation.

PROPOSITION 5. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping. Let I be an \mathbf{S} -instance. Let J be the canonical quasi-solution I w.r.t. \mathcal{M} . Let σ_1, σ_2 be distinct grounded egds in $\text{ground}(\Sigma_t, I)$ such that $J \not\models \sigma_1$ and $J \not\models \sigma_2$. Let E_1, E_2 be ideal source repair envelopes for I w.r.t. $\mathcal{M} \cup \sigma_1$ and $\mathcal{M} \cup \sigma_2$, respectively. If E_1 and E_2 are disjoint, then σ_1 and σ_2 are *pairwise-independent*.

PROOF. Suppose $E_1 \cap E_2 = \emptyset$, and let (I', J') be a canonical XR-Solution for I w.r.t. $\mathcal{M} \cup \{\sigma_1, \sigma_2\}$. Let $E'_1 = E_1 \cap I'$ and let $E'_2 = E_2 \cap I'$. By definition of a source repair envelope, $(I \setminus E_1) \cup E'_1$ is an XR-Solution for I w.r.t. $\mathcal{M} \cup \{\sigma_1\}$, and likewise $(I \setminus E_2) \cup E'_2$ is an XR-Solution for I w.r.t. $\mathcal{M} \cup \{\sigma_2\}$, and since E_1 and E_2 are disjoint, it is easy to see that E'_1 is an XR-Solution for E_1 w.r.t. $\mathcal{M} \cup \{\sigma_1, \sigma_2\}$ and E'_2 is an XR-Solution for E_2 w.r.t. $\mathcal{M} \cup \{\sigma_1, \sigma_2\}$. Finally, since GAV chase is monotone, we have that $(I \setminus E_1 \setminus E_2) \cup (E'_1) \cup (E'_2)$

has a solution w.r.t. $\mathcal{M} \cup \{\sigma_1, \sigma_2\}$, and there is no instance $I'' \subset I$ which strictly contains $(I \setminus E_1 \setminus E_2) \cup (E'_1) \cup (E'_2)$ and also has a solution w.r.t. $\mathcal{M} \cup \{\sigma_1, \sigma_2\}$. \square

We can, in polynomial time, compute the support closure for each egd violation, then compute an overapproximation of the violation clusters based on the restriction to the source schema of those closures. The next proposition follows simply from the definition of a support closure, but provides some intuition and gives a shortcut for computing a source repair envelope for a violation cluster.

PROPOSITION 6. Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping. Let I be an \mathbf{S} -instance. Let J be the canonical quasi-solution for I w.r.t. \mathcal{M} . Let $\sigma_1, \dots, \sigma_n$ be a violation cluster (so each σ_i is a ground egd where $J \not\models \sigma_i$), with support closures E_1, \dots, E_n . Then $E_1 \cup \dots \cup E_n$ is the support closure of the facts in $\sigma_1, \dots, \sigma_n$, and its \mathbf{S} -restriction is a source repair envelope for I w.r.t. $\mathcal{M}^{tgd} \cup \{\sigma_1, \dots, \sigma_n\}$

We have now seen how to compute a conservative approximation of the violation clusters for an instance w.r.t. a given schema mapping. Proposition 6 makes clear the fact that distinct violation clusters have disjoint source repair envelopes, and are therefore pairwise-independent themselves. Definition 8 tells us that we can thus compute the source repairs for an entire instance by computing separately the source repairs for the envelope of each violation cluster. We will now see how this supports query answering.

6.4 Answering Queries

We now show how to use the techniques introduced in the previous sections to compute XR-Certain answers for unions of conjunctive queries. In fact, without loss of generality, we can restrict attention to projection-free atomic queries: Let $q(\mathbf{x}) :- \phi_1(\mathbf{x}, \mathbf{y}) \vee \dots \vee \phi_n(\mathbf{x}, \mathbf{y})$ be a union of conjunctive queries with n clauses. Define t_1, \dots, t_n to be a set of new GAV tgds, where the head of each tgd is the head of q , and the body of each tgd t_k is $\phi_k(\mathbf{x}, \mathbf{y})$. If we extend a canonical quasi-solution J with the new relation symbol q , and chase with t_1, \dots, t_n , the result will be $J \cup \{q(J)\}$. We will use the notation $\text{XR-Certain}(I, \mathcal{M} \cup \{t_1, \dots, t_n\})$ to denote the set of facts in the intersection of all exchange repair solutions for I w.r.t. $\mathcal{M} \cup \{t_1, \dots, t_n\}$, and the term *candidate facts* to refer to the tuples of any relation in $\mathbf{T} \cup q$.

Consider the definition of *support sets* in Section 6.2, and suppose f is a candidate fact. By definition, f is XR-Certain if it is contained in every exchange repair solution. Since exchange repair solutions satisfy the constraints of the schema mapping, it is easy to see that f is XR-Certain if it has at least one support set in every XR-Solution, or equivalently, in every canonical XR-Solution.

Proposition 6 naturally extends to exchange repair envelopes. Thus we define a *violation cluster influence* to refer to the union of the influences of the violations in a cluster.

Example 3. This example illustrates that a candidate fact f may belong to the influences of multiple distinct violation clusters. Let $I = \{P(a_1, a_2), P(a_1, a_3), Q(a_1, a_2), Q(a_1, a_3)\}$, and let $\mathcal{M} = (\{P, Q\}, \{R, S, T\}, \{P(x, y) \rightarrow R(x, y), Q(x, y) \rightarrow S(x, y)\}, \{R(x, y) \wedge S(x, z) \rightarrow T(x, y, z), R(x, y) \wedge R(x, y') \rightarrow$

$y = y', S(x, y), S(x, y') \rightarrow y = y'\}$. Then the violation cluster influence for $\{R(a_1, a_2), R(a_1, a_3)\}$ is

$$\left\{ P(a_1, a_2), P(a_1, a_3), R(a_1, a_2), R(a_1, a_3), \right. \\ \left. T(a_1, a_2, a_3), T(a_1, a_3, a_2), T(a_1, a_2, a_2), T(a_1, a_3, a_3) \right\}$$

and the violation cluster influence for $S(a_1, a_2), S(a_1, a_3)$ is

$$\left\{ Q(a_1, a_2), Q(a_1, a_3), S(a_1, a_2), S(a_1, a_3), \right. \\ \left. T(a_1, a_2, a_3), T(a_1, a_3, a_2), T(a_1, a_2, a_2), T(a_1, a_3, a_3) \right\}$$

which are disjoint in their restriction to the source schema, yet both contain the target facts $T(a_1, a_2, a_3)$, $T(a_1, a_3, a_2)$, $T(a_1, a_2, a_2)$, and $T(a_1, a_3, a_3)$.

This example illustrates how distinct target violations with non-overlapping source repair envelopes may jointly affect target tuples; we cannot determine the status of tuples in T without considering violations of both key constraints.

Suppose f is a candidate fact in T . Each support set for f may be contained in only certain combinations of XR-Solutions from the violation cluster influences containing f . So, to determine if f has at least one support set in every XR-Solution w.r.t. the broader schema mapping, it is necessary to consider **all** combinations of XR-Solutions from the violation cluster influences containing f . We call the set of violation clusters whose influences contain f the *signature* of f , denoted $\text{signature}(f)$. Recall that I_{safe} denotes the set of source facts that are *safe*, that is, not *suspect* (Definition 5). In the following, let J_{safe} denote $\text{chase}(I_{\text{safe}}, \mathcal{M})$.

THEOREM 4. *Let $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma_{st}, \Sigma_t)$ be a GAV+(GAV, EGD) schema mapping. Let I be an \mathbf{S} -instance. Let J be the canonical quasi-solution for I w.r.t. \mathcal{M} . Let f be a candidate fact in J . Let $I_{f\text{-focus}}$ and $J_{f\text{-focus}}$ be, respectively, the source and target parts of $\bigcup\{V \mid V \text{ the influence for a violation cluster in } \text{signature}(f)\}$. Then $f \in \text{XR-Certain}(I, \mathcal{M}) \leftrightarrow f \in \bigcap\{\text{chase}(J'_{f\text{-focus}} \cup J_{\text{safe}}, \Sigma_t) \mid J'_{f\text{-focus}} \in \text{XR-Solution}(I_{f\text{-focus}}, \mathcal{M})\}$.*

PROOF SKETCH. By definition, the violations in the clusters in $\text{signature}(f)$ are contained in $J_{f\text{-focus}}$. Thus $(I_{f\text{-focus}}, J_{f\text{-focus}})$ is an exchange repair envelope for I w.r.t. \mathcal{M}^{tgd} augmented with those violations. Furthermore, all of the violations in $J_{f\text{-focus}}$ are pairwise independent of all of the violations in $J \setminus J_{f\text{-focus}}$, from which we conclude that every fact in every support set for f is contained in $(I_{f\text{-focus}}, J_{f\text{-focus}})$ or in $(I_{\text{safe}}, J_{\text{safe}})$. \square

This result gives us the following algorithm for computing XR-Certain for an instance I and schema mapping \mathcal{M} , using a (hopefully large) J_{safe} combined with, for each signature, a (hopefully small) J_{focus} . For the exchange phase: Chase I with \mathcal{M}^{tgd} , compute the violation set of I w.r.t. \mathcal{M} , and compute the support closure of each violation. Then mark source facts safe if they do not reside in any violation closure, chase I_{safe} with \mathcal{M}^{tgd} , and mark every resulting fact safe. Lastly, compute violation clusters, and the influence of each cluster. For the query phase: Compute the candidate facts, marking safe those with support sets in J_{safe} . Next, compute the signature of each unmarked candidate fact. Finally, generate and solve a grounded disjunctive logic program to compute XR-Certain w.r.t. \mathcal{M} for $(I_{\text{focus}}, J_{\text{focus}})$ for each signature. This program is the restriction to $(I_{\text{focus}}, J_{\text{focus}})$ of the grounding of the program from Theorem 2. Facts in $(I_{\text{focus}}, J_{\text{focus}}) \cap (I_{\text{safe}}, J_{\text{safe}})$ may be represented by the value TRUE in the program.

6.5 Segmentary Implementation and Results

Using the techniques developed in this section, we have implemented a *segmentary* approach to XR-Certain query answering using Java 1.7.0_80, MySQL 5.5.42, and clingo 4.4.0. Our segmentary implementation takes as input a GLAV+(WA-GLAV, EGD) schema mapping (encoded as text), an arbitrary source instance (via a JDBC connection string), and a union of conjunctive queries over the target schema (also text). As with the monolithic implementation, the schema mapping is transformed into a GAV+(GAV, EGD) schema mapping. Additionally, the query is transformed into an atomic query using the reduction described at the beginning of Section 6.4.

Using the above algorithm, query answering is done in two phases: the exchange phase, and the query phase. The exchange phase materializes the target instance in MySQL using a chase procedure written in Java. The detailed implementation of the chase procedure is immaterial: here, we use a semi-naïve chase. The exchange phase next computes violation cluster influences, fact signatures, and the “safe” part of the source and target instances (also in MySQL, run from Java). The query phase appends candidate answers to the target instance, marks “safe” candidates, and generated disjunctive logic programs as explained in Section 6.4, which are then solved using clingo. The results obtained from clingo are used to mark each candidate either “accepted” or “rejected”. The “safe” candidates and “accepted” candidates together comprise the XR-Certain query answers.

Table 4: Duration of the exchange phase, in seconds.

instance	L0	L3	L9	L20
duration	150.7	196.7	235.7	297.3
instance	S3	M3	L3	F3
duration	36.5	50.8	196.7	2229.7

Table 4 gives the runtime of the exchange phase for each instance. Notice that for large instances, the exchange phase compares very favorably against the per-query runtime of the monolithic approach described in Section 5.2. The plots in Figure 4 give the performance of each query as we scale the rate of violations and the instance size, respectively, with the latter on a log-log scale. These results improve considerably on the monolithic approach: the query phase runtimes are between ten times and one thousand times faster for large and full instances.

7. CONCLUDING REMARKS

We have implemented XR-Certain query answering and evaluated it on real data using a benchmark that mimicks the UCSC Genome Browser data import process. Our experiments suggest that using the reduction from XR-Certain to disjunctive logic programming to create a monolithic logic program is not a viable approach using today’s best-of-breed solvers. However, by efficiently computing a suitable overapproximation, our segmentary approach computes query answers ten to one thousand times faster for larger instances, and exhibits promising scalability with respect to both instance size and the rate of target constraint violations.

We note that significant progress has recently been made toward broadly applicable, reproducible schema mapping benchmarks, in particular iBench [3]. We intend as fu-

Figure 4: Performance of XR-Certain query answering using MySQL along with clingo.

ture work to further evaluate our segmentary implementation on such benchmarks. Nonetheless, our success with our Genome Browser benchmark serves as evidence that XR-Certain query answering may be efficiently computable in practice for realistic applications.

ABSTRACT

RDF is a standard for the conceptual description of knowledge, and SPARQL is the query language conceived to query RDF data. The RDF data is cherished and exploited by various domains such as life sciences, Semantic Web, social network, etc. Further, its integration at Web-scale compels RDF management engines to deal with complex queries in terms of both size and structure. In this paper, we propose AMBER (Attributed Multigraph Based Engine for RDF querying), a novel RDF query engine specifically designed to optimize the computation of complex queries. AMBER leverages subgraph matching techniques and extends them to tackle the SPARQL query problem. First of all RDF data is represented as a multigraph, and then novel indexing structures are established to efficiently access the information from the multigraph. Finally a SPARQL query is represented as a multigraph, and the SPARQL querying problem is reduced to the subgraph homomorphism problem. AMBER exploits structural properties of the query multigraph as well as the proposed indexes, in order to tackle the problem of subgraph homomorphism. The performance of AMBER, in comparison with state-of-the-art systems, has been extensively evaluated over several RDF benchmarks. The advantages of employing AMBER for complex SPARQL queries have been experimentally validated.

1. INTRODUCTION

In the recent years, structured knowledge represented in the form of RDF data has been increasingly adopted to improve the robustness and the performances of a wide range of applications with various purposes. Popular examples are provided by Google, that exploits the so called *knowledge graph* to enhance its search results with semantic information gathered from a wide variety of sources, or by Facebook, that implements the so called *entity graph* to empower its search engine and provide further information extracted, for

instance by Wikipedia. Another example is supplied by recent question-answering systems [4, 15] that automatically translate natural language questions in SPARQL queries and successively retrieve answers considering the available information in the different Linked Open Data sources. In all these examples, complex queries (in terms of size and structure) are generated to ensure the retrieval of all the required information. Thus, as the use of large knowledge bases, that are commonly stored as RDF triplets, is becoming a common way to ameliorate a wide range of applications, efficient querying of RDF data sources using SPARQL is becoming crucial for modern information retrieval systems.

All these different scenarios pose new challenges to the RDF query engines for two vital reasons: firstly, the automatically generated queries cannot be bounded in their structural complexity and size (e.g., the DBPEDIA SPARQL Benchmark [12] contains some queries having more than 50 triplets [1]); secondly, the queries generated by retrieval systems (or by any other applications) need to be efficiently answered in a reasonable amount of time. Modern RDF data management, such as *x-RDF-3X* [13] and *Virtuoso* [7], are designed to address the scalability of SPARQL queries but they still have problems to answer big and structurally complex SPARQL queries [2]. Our experiments with state-of-the-art systems demonstrate that they fail to efficiently manage such kind of queries (Table 1).

Systems	AMBER	<i>gStore</i>	<i>Virtuoso</i>	<i>x-RDF-3X</i>
Time (sec)	1.56	11.96	20.45	>60

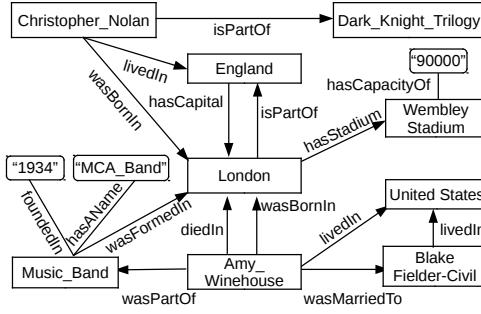

Table 1: Average Time (seconds) for a sample of 200 complex queries on *DBPEDIA*. Each query has 50 triplets.

In order to tackle these issues, in this paper, we introduce AMBER (Attributed Multigraph Based Engine for RDF querying), which is a graph-based RDF engine that involves two steps: an offline stage where RDF data is transformed into multigraph and indexed, and an online step where an efficient approach to answer SPARQL query is proposed. First of all RDF data is represented as a multigraph where subjects/objects constitute vertices and multiple edges (predicates) can appear between the same pair of vertices. Then, new indexing structures are conceived to efficiently access RDF multigraph information. Finally, by representing the SPARQL queries also as multigraphs, the query answering

task can be reduced to the problem of subgraph homomorphism. To deal with this problem, AMBER employs an efficient approach that exploits structural properties of the multigraph query as well as the indices previously built on the multigraph structure. Experimental evaluation over popular RDF benchmarks show the quality in terms of time performances and robustness of our proposal.

In this paper, we focus only on the **SELECT/WHERE** clause of the SPARQL language¹, that constitutes the most important operation of any RDF query engines. It is out of the scope of this work to consider operators like **FILTER**, **UNION** and **GROUP BY** or manage RDF update. Such operations can be addressed in future as extensions of the current work.

The paper is organized as follows. Section 2 introduces the basic notions about RDF and SPARQL language. In Section 3 AMBER is presented. Section 4 describes the indexing strategy while Section 5 presents the query processing. Related works are discussed in Section 6. Section 7 provides the experimental evaluation. Section 8 concludes.

2. BACKGROUND AND PRELIMINARIES

In this section we provide basic definitions on the interplay between RDF and its multigraph representation. Later, we explain how the task of answering SPARQL queries can be reduced to multigraph homomorphism problem.

2.1 RDF Data

As per the W3C standards², RDF data is represented as a set of triples $\langle S, P, O \rangle$, as shown in Figure 1a, where each triple $\langle s, p, o \rangle$ consists of three components: a *subject*, a *predicate* and an *object*. Further, each component of the RDF triple can be of any two forms; an *IRI* (Internationalized Resource Identifier) or a literal. For brevity, an *IRI* is usually written along with a prefix (e.g., $\langle \text{http://dbpedia.}$

$\text{org/resource/isPartOf} \rangle$ is written as 'x:isPartOf'), whereas a literal is always written with double quotes (e.g., "90000"). While a subject s and a predicate p are always an *IRI*, an object o is either an *IRI* or a literal.

RDF data can also be represented as a directed graph where, given a triple $\langle s, p, o \rangle$, the subject s and the object o can be treated as vertices and the predicate p forms a directed edge from s to o , as depicted in Figure 1b. Further, to underline the difference between an *IRI* and a literal, we use standard rectangles and arc for the former while we use beveled corner and edge (no arrows) for the latter.

2.1.1 Data Multigraph Representation

Motivated by the graph representation of RDF data (Figure 1b), we take a step further by transforming it to a data multigraph G , as shown in Figure 1c.

Let us consider an RDF triple $\langle s, p, o \rangle$ from the RDF tripleaset $\langle S, P, O \rangle$. Now to transform the RDF tripleaset into data multigraph G , we set four protocols: we always treat the subject s as a vertex; a predicate p is always treated as an edge; we treat the object o as a vertex only if it is an *IRI* (e.g., vertex v_2 corresponds to object 'x:London'); when the object is a literal, we combine the object o and the corresponding predicate p to form a tuple $\langle p, o \rangle$ and assign it as an attribute to the subject s (e.g., $\langle \text{'y:hasCapacityOf'}, \text{'90000'} \rangle$ is assigned to vertex v_4). Every vertex is assigned a null value $\{-\}$ in the attribute set. However, to realize this in the realms of graph management techniques, we maintain three different dictionaries, whose elements are a pair of 'key' and 'value', and a mapping function that links them. The three dictionaries depicted in Table 2 are: a vertex dictionary (Table 2a), an edge-type dictionary (Table 2b) and an attribute dictionary (Table 2c). In all the three dictionaries, an RDF entity represented by a 'key' is mapped to a corresponding 'value', which can be a vertex/edge/attribute identifier. Thus by using the mapping functions - \mathcal{M}_v , \mathcal{M}_e , and \mathcal{M}_a for vertex, edge-type and attribute mapping respectively, we obtain a directed, vertex attributed data multi-

¹<http://www.w3.org/TR/sparql11-overview/>

²<http://www.w3.org/TR/2014/REC-rdf11-concepts-20140225/>

graph G (Figure 1c), which is formally defined as follows.

DEFINITION 1. Directed, Vertex Attributed Multigraph. A directed, vertex attributed multigraph G is defined as a 4-tuple (V, E, L_V, L_E) where V is a set of vertices, $E \subseteq V \times V$ is a set of directed edges with $(v, v') \neq (v', v)$, L_V is a labelling function that assigns a subset of vertex attributes A to the set of vertices V , and L_E is a labelling function that assigns a subset of edge-types T to the edge set E .

To summarise, an RDF triplesets is transformed into a data multigraph G , whose elements are obtained by using the mapping functions as already discussed. Thus, the set of vertices $V = \{v_0, \dots, v_m\}$ is the set of mapped subject/object *IRI*, and the labelling function L_V assigns a set of vertex attributes $A = \{-, a_0, \dots, a_n\}$ (mapped tuple of predicate and object-literal) to the vertex set V . The set of directed edges E is a set of pair of vertices (v, v') that are linked by a predicate, and the labelling function L_E assigns the set of edge types $T = \{t_0, \dots, t_p\}$ (mapped predicates) to these set of edges. The edge set E maintains the topological structure of the RDF data. Further, mapping of object-literals and the corresponding predicates as a set of vertex attributes, results in a compact representation of the multigraph. For example (in Fig. 1c), all the object-literals and the corresponding predicates are reduced to a set of vertex attributes.

2.2 SPARQL Query

A SPARQL query usually contains a set of triple patterns, much like RDF triples, except that any of the subject, predicate and object may be a variable, whose bindings are to be found in the RDF data³. In the current work, we address the SPARQL queries with ‘SELECT/WHERE’ option, where the predicate is always instantiated as an *IRI* (Figure 2a). The **SELECT** clause identifies the variables to appear in the query results while the **WHERE** clause provides triple patterns to match against the RDF data.

2.2.1 Query Multigraph Representation

In any valid SPARQL query (as in Figure 2a), every triplet has at least one unknown variable $?X$, whose bindings are to be found in the RDF data. It should now be easy to observe that a SPARQL query can be represented in the form of a graph as in Figure 2b, which in turn is transformed into query multigraph Q (as in Figure 2c).

In the query multigraph representation, each unknown variable $?X_i$ is mapped to a vertex u_i that forms the vertex set U component of the query multigraph Q (e.g., $?X_6$ is mapped to u_6). Since a predicate is always instantiated as an *IRI*, we use the edge-type dictionary in Table 2b, to map the predicate to an edge-type identifier $t_i \in T$ (e.g., ‘isMarriedTo’ is mapped as t_8). When an object o_i is a literal, we use the attribute dictionary (Table 2c), to find the attribute identifier a_i for the predicate-object tuple $\langle p_i, o_i \rangle$ (e.g., $\{a_0\}$ forms the attribute for vertex u_4). Further, when a subject or an object is an *IRI*, which is a not a variable, we use the vertex dictionary (2a), to map it to an *IRI*-vertex u_i^{iri} (e.g., ‘x:United_States’ is mapped to u_0^{iri}) and maintain a set of *IRI* vertices R . Since this vertex is not a variable and a real vertex of the query, we portray it differently by a shaded square shaped vertex. When a query vertex u_i does

not have any vertex attributes associated with it (e.g., u_0, u_1, u_2, u_3, u_6), a null attribute $\{-\}$ is assigned to it. On the other hand, an *IRI*-vertex $u_i^{iri} \in R$ does not have any attributes. Thus, a SPARQL query is transformed into a query multigraph Q .

In this work, we always use the notation V for the set of vertices of G , and U for the set of vertices of Q . Consequently, a data vertex $v \in V$, and a query vertex $u \in U$. Also, an incoming edge to a vertex is positive (default), and an outgoing edge from a vertex is labelled negative ($^{-}$).

2.3 SPARQL Querying by Adopting Multigraph Homomorphism

As we recall, the problem of SPARQL querying is addressed by finding the solutions to the unknown variables $?X$, that can be bound with the RDF data entities, so that the relations (predicates) provided in the SPARQL query are respected. In this work, to harness the transformed data multigraph G and the query multigraph Q , we reduce the problem of SPARQL querying to a sub-multigraph homomorphism problem. The RDF data is transformed into data multigraph G and the SPARQL query is transformed into query multigraph Q . Let us now recall that finding SPARQL answers in the RDF data is equivalent to finding all the sub-multigraphs of Q in G that are homomorphic. Thus, let us now formally introduce homomorphism for a vertex attributed, directed multigraph.

DEFINITION 2. Sub-multigraph Homomorphism. Given a query multigraph $Q = (U, E^Q, L_U, L_E^Q)$ and a data multigraph $G = (V, E, L_V, L_E)$, the sub-multigraph homomorphism from Q to G is a surjective function $\psi : U \rightarrow V$ such that:

1. $\forall u \in U, L_U(u) \subseteq L_V(\psi(u))$
2. $\forall (u_m, u_n) \in E^Q, \exists (\psi(u_m), \psi(u_n)) \in E$, where (u_m, u_n) is a directed edge, and $L_E^Q(u_m, u_n) \subseteq L_E(\psi(u_m), \psi(u_n))$.

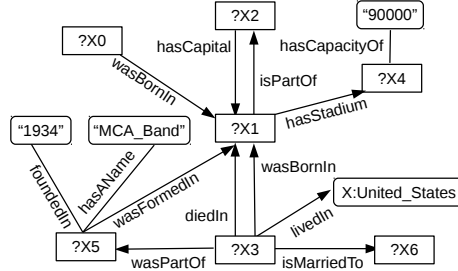

Thus, by finding all the sub-multigraphs in G that are homomorphic to Q , we enumerate all possible homomorphic embeddings of Q in G . These embeddings contain the solution for each of the query vertex that is an unknown variable. Thus, by using the inverse mapping function $\mathcal{M}_v^{-1}(v_i)$ (introduced already), we find the bindings for the SPARQL

query. The decision problem of subgraph homomorphism is NP-complete. This standard subgraph homomorphism problem can be seen as a particular case of sub-multigraph homomorphism, where both the labelling functions L_E and L_E^Q always return the same subset of edge-types for all the edges in both Q and G . Thus the problem of sub-multigraph homomorphism is at least as hard as subgraph homomorphism. Further, the subgraph homomorphism problem is a generic scenario of subgraph isomorphism problem where, the injectivity constraints are slackened [11].

3. AMBER: A SPARQL QUERYING ENGINE

We now present an overview of our proposal - AMBER (Attributed Multigraph Based Engine for RDF querying). AMBER contains two different stages: (i) an offline stage during which, RDF data is transformed into multigraph G and then a set of index structures \mathcal{I} is constructed that captures the necessary information contained in G ; (ii) an online stage during which, a SPARQL query is transformed into a multigraph Q , and then by exploiting the subgraph matching techniques along with the already built index structures \mathcal{I} , the homomorphic matches of Q in G are obtained.

Given a multigraph representation Q of a SPARQL query, AMBER decomposes the query vertices U into a set of core vertices U_c and satellite vertices U_s . Intuitively, a vertex $u \in U$ is a core vertex, if the degree of the vertex is more than one; on the other hand, a vertex u with degree one is a satellite vertex. For example, in Figure 2c, $U_c = \{u_1, u_3, u_5\}$ and $U_s = \{u_0, u_2, u_4, u_6\}$. Once decomposed, we run the sub-multigraph matching procedure on the query structure spanned only by the core vertices. However, during the procedure, we also process the satellite vertices (if available) that are connected to a core vertex that is being processed. For example, while processing the core vertex u_1 , we also process the set of satellite vertices $\{u_0, u_2, u_4\}$ connected to it; whereas, the core vertex u_5 has no satellite vertices to be processed. In this way, as the matching proceeds, the entire structure of the query multigraph Q is processed to find the homomorphic embeddings in G . The set of indexing structures \mathcal{I} are extensively used during the process of sub-multigraph matching. The homomorphic embeddings are finally translated back to the RDF entities using the inverse mapping function \mathcal{M}_v^{-1} as discussed in Section 2.

4. INDEX CONSTRUCTION

Given a data multigraph G , we build the following three different indices: (i) an inverted list \mathcal{A} for storing the set of data vertex for each attribute in $a_i \in A$ (ii) a trie index structure \mathcal{S} to store features of all the data vertices V (iii) a set of trie index structures \mathcal{N} to store the neighbourhood information of each data vertex $v \in V$. For brevity of representation, we ensemble all the three index structures into $\mathcal{I} := \{\mathcal{A}, \mathcal{S}, \mathcal{N}\}$.

During the query matching procedure (the online step), we access these indexing structures to obtain the candidate solutions for a query vertex u . Formally, for a query vertex u , the *candidate solutions* are a set of data vertices $C_u = \{v | v \in V\}$ obtained by accessing \mathcal{A} or \mathcal{S} or \mathcal{N} , denoted as $C_u^{\mathcal{A}}$, $C_u^{\mathcal{S}}$ and $C_u^{\mathcal{N}}$ respectively.

4.1 Attribute Index

The set of vertex attributes is given by $A = \{a_0, \dots, a_n\}$ (Section 2), where a data vertex $v \in V$ might have a subset of A assigned to it. We now build the vertex attribute index \mathcal{A} by creating an inverted list where a particular attribute a_i has the list of all the data vertices in which it appears.

Given a query vertex u with a set of vertex attributes $u.A \subseteq A$, for each attribute $a_i \in u.A$, we access the index structure \mathcal{A} to fetch a set of data vertices that have a_i . Then we find a common set of data vertices that have the entire attribute set $u.A$. For example, considering the query vertex u_5 (Fig. 2c), it has an attribute set $\{a_1, a_2\}$. The candidate solutions for u_5 are obtained by finding all the common data vertices, in \mathcal{A} , between a_1 and a_2 , resulting in $C_{u_5}^{\mathcal{A}} = \{u_0\}$.

4.2 Vertex Signature Index

The index \mathcal{S} captures the edge type information from the data vertices. For a lucid understanding of this indexing schema we formally introduce the notion of vertex signature that is defined for a vertex $v \in V$, which encapsulates the edge information associated with it.

DEFINITION 3. Vertex signature. *For a vertex $v \in V$, the vertex signature σ_v is a multiset containing all the directed multi-edges that are incident on v , where a multi-edge between v and a neighbouring vertex v' is represented by a set that corresponds to the edge types. Formally, $\sigma_v = \bigcup_{v' \in N(v)} L_E(v, v')$ where $N(v)$ is the set of neighbourhood vertices of v , and \cup is the union operator for multiset.*

Data vertex	Signature	Synopsis							
v	σ_v	f_1^+	f_2^+	f_3^+	f_4^+	f_1^-	f_2^-	f_3^-	f_4^-
v_0	$\{\{-t_6\}, \{t_7\}\}$	1	1	-7	7	1	1	-6	6
v_1	$\{\{-t_3\}, \{-t_7\}, \{-t_8\}, \{-t_4, -t_5\}\}$	0	0	0	0	2	5	-3	8
v_2	$\{\{-t_0\}, \{t_1\}, \{-t_2\}, \{t_5\}, \{t_6\}, \{t_4, t_5\}\}$	2	4	-1	6	1	2	0	2
v_3	$\{\{t_0\}, \{t_3\}, \{-t_1\}\}$	1	2	0	3	1	1	-1	1
v_4	$\{\{t_2\}\}$	1	1	-2	2	0	0	0	0
v_5	$\{\{t_3\}, \{t_3\}\}$	1	1	-3	3	0	0	0	0
v_6	$\{\{t_8\}, \{-t_3\}\}$	1	1	-8	8	1	1	-3	3
v_7	$\{\{-t_0\}, \{-t_3\}, \{-t_5\}\}$	0	0	0	0	1	3	0	5
v_8	$\{\{t_0\}\}$	1	1	0	0	0	0	0	0

Table 3: Vertex signatures and the corresponding synopses for the vertices in the data multigraph G (Figure 1c)

The index \mathcal{S} is constructed by tailoring the information supplied by the vertex signature of each vertex in G . To extract some interesting features, let us observe the vertex signature σ_{v_2} as supplied in Table 3. To begin with, we can represent the vertex signature σ_{v_2} separately for the incoming and outgoing multi-edges as $\sigma_{v_2}^+ = \{\{t_1\}, \{t_5\}, \{t_6\}, \{t_4, t_5\}\}$ and $\sigma_{v_2}^- = \{\{-t_0\}, \{-t_2\}\}$ respectively. Now we observe that $\sigma_{v_2}^+$ has four distinct multi-edges and $\sigma_{v_2}^-$ has two distinct multi-edges. Now, let's think that we want to find candidate solutions for a query vertex u . The data vertex v_2 can be a match for u only if the signature of u has at most four incoming ('+') edges and at most two outgoing ('-') edges; else v_2 can not be a match for u . Thus, more such features (e.g., maximum cardinality of a set in the vertex signature) can be proposed to filter out irrelevant candidate vertices. Thus, for each vertex v , we propose to extract a set of features by exploiting the corresponding vertex signature. These features constitute a *synopses*, which is a surrogate representation that approximately captures the vertex signature information.

The synopsis of a vertex v contains a set of features F , whose values are computed from the vertex signature σ_v . In this background, we propose four distinct features: f_1 - the maximum cardinality of a set in the vertex signature; f_2 - the number of unique dimensions in the vertex signature; f_3 - the minimum index value of the edge type; f_4 - the maximum index value of the edge type. For f_3 and f_4 , the index values of edge type are nothing but the position of the sequenced alphabet. These four basic features are replicated separately for outgoing (negative) and incoming (positive) edges, as seen in Table 3. Thus for the vertex v_2 , we obtain $f_1^+ = 2$, $f_2^+ = 4$, $f_3^+ = -1$ and $f_4^+ = 7$ for the incoming edge set and $f_1^- = 1$, $f_2^- = 2$, $f_3^- = 0$ and $f_4^- = 2$ for the outgoing edge set. Synopses for the entire vertex set V for the data multigraph G are depicted in Table 3.

Once the synopses are computed for all data vertices, an R-tree is constructed to store all the synopses. This R-tree constitutes the vertex signature index \mathcal{S} . A synopsis with $|F|$ fields forms a leaf in the R-tree.

When a set of possible candidate solutions are to be obtained for a query vertex u , we create a vertex signature σ_u in order to compute the synopsis, and then obtain the possible solutions from the R-tree structure.

The general idea of using an R-tree is as follows. A synopsis F of a data vertex spans an axes-parallel rectangle in an $|F|$ -dimensional space, where the maximum co-ordinates of the rectangle are the values of the synopses

fields $(f_1, \dots, f_{|F|})$, and the minimum co-ordinates are the origin of the rectangle (filled with zero values). For example, a data vertex represented by a synopsis with two features $F(v) = [2, 3]$ spans a rectangle in a 2-dimensional space in the interval range $([0, 2], [0, 3])$. Now, if we consider synopses of two query vertices, $F(u_1) = [1, 3]$ and $F(u_2) = [1, 4]$, we observe that the rectangle spanned by $F(u_1)$ is wholly contained in the rectangle spanned by $F(v)$ but $F(u_2)$ is not wholly contained in $F(v)$. Thus, u_1 is a candidate match while u_2 is not.

LEMMA 1. *Querying the vertex signature index \mathcal{S} constructed with synopses, guarantees to output at least the entire set of candidate solutions.*

PROOF. Consider the field f_1^+ in the synopses that represents the maximum cardinality of the neighbourhood signature. Let σ_u be the signature of the query vertex u and $\{\sigma_{v_1}, \dots, \sigma_{v_n}\}$ be the set of signatures on the data vertices. By using f_1 we need to show that C_u^S has at least all the valid candidate matches. Since we are looking for a superset of query vertex signature, and we are checking the condition $f_1^+(u) \leq f_1^+(v_i)$, where $v_i \in V$, a vertex v_i is pruned if it does not match the inequality criterion since, it can never be an eligible candidate. This analogy can be extended to the entire synopses, since it can be applied disjunctively. \square

Formally, the candidates solutions for a vertex u can be written as $C_u^S = \{v | \forall i \in [1, \dots, |F|] f_i^\pm(u) \leq f_i^\pm(v)\}$, where the constraints are met for all the $|F|$ -dimensions. Since we apply the same inequality constraint to all the fields, we negate the fields that refer to the minimal index value of the edge type (f_3^+ and f_3^-) so that the rectangular containment problem still holds good. Further to respect the rectangular containment, we populate the synopses fields with '0' values, in case, the signature does not have either positive or negative edges in it, as seen for v_1, v_3, v_4, v_5 and v_7 .

For example, if we want to compute the possible candidates for a query vertex u_0 in Figure 2c, whose signature is $\sigma_{u_0} = \{-t_5\}$, we compute the synopsis which is $[0 \ 0 \ 0 \ 0 \ 1 \ 1 \ 5 \ 5]$. Now we look for all those vertices that subsume this synopsis in the R-tree, whose elements are depicted in Table 3, which gives us the candidate solutions $C_{u_0}^S = \{v_1, v_7\}$, thus pruning the rest of the vertices.

The \mathcal{S} index helps to prune the vertices that do not respect the edge type constraints. This is crucial since this pruning is performed for the initial query vertex, and hence many candidates are cast away, thereby avoiding unnecessary recursion during the matching procedure. For example,

for the initial query vertex u_0 , whose candidate solutions are $\{v_1, v_7\}$, the recursion branch is run only on these two starting vertices instead of the entire vertex set V .

4.3 Vertex Neighbourhood Index

The *vertex neighbourhood index* \mathcal{N} captures the topological structure of the data multigraph G . The index \mathcal{N} comprises of 1-neighbourhood trees built for each data vertex $v \in V$. Since G is a directed multigraph, and each vertex $v \in V$ can have both the incoming and outgoing edges, we construct two separate index structures \mathcal{N}^+ and \mathcal{N}^- for incoming and outgoing edges respectively, that constitute the structure \mathcal{N} .

To understand the index structure, let us consider the data vertex v_2 from Figure 1c, shown separately in Figure 3a. For this vertex v_2 , we collect all the neighbourhood information (vertices and multi-edges), and represent this information by a tree structure, built separately for incoming ('+') and outgoing ('-') edges. Thus, the tree representation of a vertex v contains the neighbourhood vertices and the corresponding multi-edges, as shown in Figure 3b, where the vertices of the tree structure are represented by the edge types.

Figure 3: Building Neighbourhood Index for data vertex v_2

In order to construct an efficient tree structure, we take inspiration from [14] to propose the structure - Ordered Trie with Inverted List (OTIL). To construct the OTIL index as shown in Figure 3b, we insert each ordered multi-edge that is incident on v at the root of the trie. Consider a data vertex v_i , with a set of n neighbourhood vertices $N(v_i)$. Now, for every pair of incoming edge $(v_i, N^j(v_i))$, where $j \in \{1, \dots, n\}$, there exists a multi-edge $\{t_i, \dots, t_j\}$, which is inserted into the OTIL structure \mathcal{N}^+ . Similarly for every pair of outgoing edge $(N^j(v_i), v_i)$, there exists a multi-edge $\{t_m, \dots, t_n\}$, which is inserted into the OTIL structure \mathcal{N}^- maintaining two OTIL structures that constitute \mathcal{N} . Each multi-edge is ordered (w.r.t. increasing edge type indexes), before inserting into the respective OTIL structure, and the order is universally maintained for all data vertices. Further, for every edge type t_i , we maintain a *list* that contains all the neighbourhood vertices $N^+(v_i)/N^-(v_i)$, that have the edge type t_i incident on them.

To understand the utility of \mathcal{N} , let us consider an illustrative example. Considering the query multigraph in Figure 2c, let us assume that we want to find the matches for the query vertices u_1 and u_0 in order. Thus, for the initial vertex u_1 , let us say, we have found the set of candidate solutions which is $\{v_2\}$. Now, to find the candidate solutions for the next query vertex u_0 , it is important to maintain the structure spanned by the query vertices, and this is where the indexing structure \mathcal{N} is accessed. Thus to retain the structure of the query multigraph (in this case, the struc-

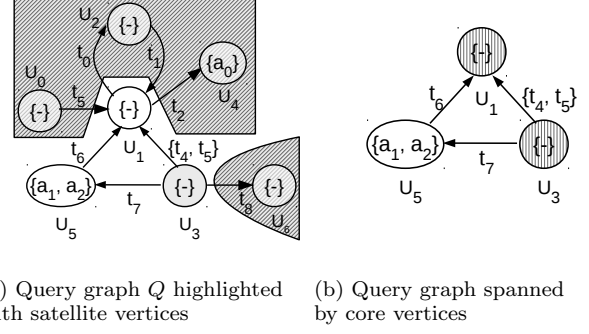

Figure 4: Decomposing the query multigraph into *core* and *satellite* vertices

ture between u_1 and u_0), we have to find the data vertices that are in the neighbourhood of already matched vertex v_2 (a match for vertex u_1), that has the same structure (edge types) between u_1 and u_0 in the query graph. Thus to fetch all the data vertices that have the edge type t_5 , which is directed towards v_2 and hence '+', we access the neighbourhood index trie \mathcal{N}^+ for vertex v_2 , as shown in Figure 3. This gives us a set of candidate solutions $C_{u_0}^{\mathcal{N}} = \{v_1, v_7\}$. It is easy to observe that, by maintaining two separate indexing structures \mathcal{N}^+ and \mathcal{N}^- , for both incoming and outgoing edges, we can reduce the time to fetch the candidate solutions.

Thus, in a generic scenario, given an already matched data vertex v , the edge direction '+' or '-', and the set of edge types $T' \subseteq T$, the index \mathcal{N} will find a set of neighbourhood data vertices $\{v' | (v', v) \in E \wedge T' \subseteq L_E(v', v)\}$ if the edge direction is '+' (incoming), while \mathcal{N} returns $\{v' | (v, v') \in E \wedge T' \subseteq L_E(v, v')\}$ if the edge direction is '-' (outgoing).

5. QUERY MATCHING PROCEDURE

In order to follow the working of the proposed query matching procedure, we formalize the notion of *core* and *satellite* vertices. Given a query graph Q , we decompose the set of query vertices U into a set of *core* vertices U_c and a set of *satellite* vertices U_s . Formally, when the degree of the query graph $\Delta(Q) > 1$, $U_c = \{u | u \in U \wedge \deg(u) > 1\}$; however, when $\Delta(Q) = 1$, i.e., when the query graph is either a vertex or a multiedge, we choose one query vertex at random as a *core* vertex, and hence $|U_c| = 1$. The remaining vertices are classified as *satellite* vertices, whose degree is always 1. Formally, $U_s = \{U \setminus U_c\}$, where for every $u \in U_s$, $\deg(u) = 1$. The decomposition for the query multigraph Q is depicted in Figure 4, where the *satellite* vertices are separated (vertices under the shaded region in Fig. 4a), in order to obtain the query graph that is spanned only by the *core* vertices (Fig. 4b).

The proposed AMBER-Algo (Algorithm 3) performs recursive sub-multigraph matching procedure only on the query structure spanned by U_c as seen in Figure 4b. Since the entire set of *satellite* vertices U_s is connected to the query structure spanned by the *core* vertices, AMBER-Algo processes the *satellite* vertices while performing sub-multigraph matching on the set of *core* vertices. Thus during the recursion, if the current *core* vertex has *satellite* vertices connected to it, the algorithm retrieves directly a list of possible matching for such *satellite* vertices and it includes them in

the current partial solution. Each time the algorithm executes a recursion branch with a solution, the solution not only contains a data vertex match v_c for each query vertex belonging to U_c , but also a set of matched data vertices V_s for each query vertex belonging to U_s . Each time a solution is found, we can generate not only one, but a set of embeddings through the Cartesian product of the matched elements in the solution.

Since finding SPARQL solutions is equivalent to finding homomorphic embeddings of the query multigraph, the homomorphic matching allows different query vertices to be matched with the same data vertices. Recall that there is no injectivity constraint in sub-multigraph homomorphism as opposed to sub-multigraph isomorphism [11]. Thus during the recursive matching procedure, we do not have to check if the potential data vertex has already been matched with previously matched query vertices. This is an advantage when we are processing satellite vertices: we can find matches for each satellite vertex independently without the necessity to check for a repeated data vertex.

Before getting into the details of the AMBER-Algo, we first explain how a set of candidate solutions is obtained when there is information associated only with the vertices. Then we explain how a set of candidate solutions is obtained when we encounter the satellite vertices.

5.1 Vertex Level Processing

To understand the generic query processing, it is necessary to understand the matching process at vertex level. Whenever a query vertex $u \in U$ is being processed, we need to check if u has a set of attributes A associated with it or any *IRI*s are connected to it (recall Section 2.2).

Algorithm 1: PROCESSVERTEX($u, Q, \mathcal{A}, \mathcal{N}$)

```

1 if  $u.A \neq \emptyset$  then
2    $C_u^A = \text{QUERYATTINDEX}(\mathcal{A}, u.A)$ 
3 if  $u.R \neq \emptyset$  then
4    $C_u^I = \bigcap_{u_i^{iri} \in u.R} (\text{QUERYNEIGHINDEX}(\mathcal{N}, L_E^Q(u, u_i^{iri}), u_i^{iri}))$ 
5  $\text{CandAtt}_u = C_u^A \cap C_u^I$  /* Find common candidates */
6 return  $\text{CandAtt}_u$ 

```

To process an arbitrary query vertex, we propose a procedure PROCESSVERTEX, depicted in Algorithm 1. This algorithm is invoked only when a vertex u has at least, either a set of vertex attributes or any *IRI* associated with it. The PROCESSVERTEX procedure returns a set of data vertices CandAtt_u , which are matchable with u ; in case CandAtt_u is empty, then the query vertex u has no matches in V .

As seen in Lines 1-2, when a query vertex u has a set of vertex attributes i.e., $u.A \neq \emptyset$, we obtain the candidate solutions C_u^A by invoking QUERYATTINDEX procedure, that accesses the index \mathcal{A} as explained in Section 4.1. For example, the query vertex u_5 with vertex attributes $\{a_1, a_2\}$, can only be matched with the data vertex v_0 ; thus $C_{u_5}^A = \{v_0\}$.

When a query vertex u has *IRI*s associated with it, i.e., $u.R \neq \emptyset$ (Lines 3-4), we find the candidate solutions C_u^I by invoking the QUERYNEIGHINDEX procedure. As we recall from Section 2.2, a vertex u is connected to an *IRI* vertex u_i^{iri} through a multi-edge $L_E^Q(u, u_i^{iri})$. An *IRI* vertex u_i^{iri} always has only one data vertex v , that can match. Thus, the candidate solutions C_u^I are obtained by invoking the QUERYNEIGHINDEX procedure, that fetches all the neigh-

Figure 5: A star structure in the query multigraph Q

bourhood vertices of v that respect the multi-edge $L_E^Q(u, u_i^{iri})$. The procedure is invoked until all the *IRI* vertices $u.R$ are processed (Line 4). Considering the example in Figure 2c, u_3 is connected to an *IRI*-vertex u_0^{iri} , which has a unique data vertex match v_5 , through the multi-edge $\{-t_3\}$. Using the neighbourhood index \mathcal{N} , we look for the neighbourhood vertices of v_5 , that have the multi-edge $\{-t_3\}$, which gives us the candidate solutions $C_{u_3}^I = \{v_1\}$.

Finally in Line 5, the merge operator \cap returns a set of common candidates CandAtt_u , only if $u.A \neq \emptyset$ and $u.R \neq \emptyset$. Otherwise, C_u^A or C_u^I are returned as CandAtt_u .

5.2 Processing Satellite Vertices

In this section, we provide insights on processing a set of satellite vertices $U_{sat} \subseteq U_s$ that are connected to a core vertex $u_c \in U_c$. This scenario results in a structure that appears frequently in SPARQL queries called star structure [8, 10].

A typical star structure depicted in Figure 5, has a core vertex $u_c = u_1$, and a set of satellite vertices $U_{sat} = \{u_0, u_2, u_4\}$ connected to the core vertex. For each candidate solution of the core vertex u_1 , we process u_0, u_2, u_4 independently of each other, since there is no structural connectivity (edges) among them, although they are only structurally connected to the core vertex u_1 .

LEMMA 2. *For a given star structure in a query graph, each satellite vertex can be independently processed if a candidate solution is provided for the core vertex u_c .*

PROOF. Consider a core vertex u_c that is connected to a set of satellite vertices $U_{sat} = \{u_0, \dots, u_s\}$, through a set of edge-types $T' = \{t_0, \dots, t_s\}$. Let us assume v_c is a candidate solution for the core vertex u_c , and we want to find candidate solutions for $u_i \in U_{sat}$ and $u_j \in U_{sat}$, where $i \neq j$. Now, the candidate solutions for u_i and u_j can be obtained by fetching the neighbourhoods of already matched vertex v_c that respect the edge-type $t_i \in T'$ and $t_j \in T'$ respectively. Since two satellite vertices u_i and u_j are never connected to each other, the candidate solutions of u_i are independent of that of u_j . This analogy applies to all the satellite vertices. \square

Given a core vertex u_c , we initially find a set of candidate solutions Cand_{u_c} , by using the index \mathcal{S} . Then, for each candidate solution $v_c \in \text{Cand}_{u_c}$, the set of solutions for all the satellite vertices U_{sat} that are connected to u_c are returned by the MATCHSATVERTICES procedure, described in Algorithm 2. The set of solution tuple M_{sat} defined in Line 1, stores the candidate solutions for the entire set of satellite vertices U_{sat} . Formally, $M_{sat} = \{[u_s, V_s]\}_{s=1}^{|U_{sat}|}$, where $u_s \in U_{sat}$ and V_s is a set of candidate solutions for u_s . In order to obtain candidate solutions for u_s , we query the

Algorithm 2: MATCHSATVERTICES($\mathcal{A}, \mathcal{N}, Q, U_{sat}, v_c$)

```

1 SET:  $M_{sat} = \emptyset$ , where  $M_{sat} = \{[u_s, V_s]\}_{s=1}^{|U_{sat}|}$ 
2 for all  $u_s \in U_{sat}$  do
3    $Cand_{u_s} = \text{QUERYNEIGHINDEX}(\mathcal{N}, L_E^Q(u_c, u_s), v_c)$ 
4    $Cand_{u_s} = Cand_{u_s} \cap \text{PROCESSVERTEX}(u_s, Q, \mathcal{A}, \mathcal{N})$ 
5   if  $Cand_{u_s} \neq \emptyset$  then
6      $M_{sat} = M_{sat} \cup (u_s, Cand_{u_s})$  /* Satellite solutions */
7   else
8     return  $M_{sat} := 0$  /* No solutions possible */
9 return  $M_{sat}$  /* Matches for satellite vertices */

```

neighbourhood index \mathcal{N} (Line 3); the QUERYNEIGHINDEX function obtains all the neighbourhood vertices of already matched v_c , that also considers the multi-edge in the query multigraph $L_E^Q(u_c, u_s)$. As every query vertex $u_s \in U_{sat}$ is processed, the solution set M_{sat} that contains candidate solutions grows until all the satellite vertices have been processed (Lines 2-8).

In Line 4, the set of candidate solutions $Cand_{u_s}$ are refined by invoking Algorithm 1 (VERTEXPROCESSING). After the refinement, if there are finite candidate solutions, we update the solution M_{sat} ; else, we terminate the procedure as there can be no matches for a given matched vertex v_c . The MATCHSATVERTICES procedure performs two tasks: firstly, it checks if the candidate vertex $v_c \in Cand_{u_s}$ is a valid matchable vertex and secondly, it obtains the solutions for all the satellite vertices.

5.3 Arbitrary Query Processing

Algorithm 3 shows the generic procedure we develop to process arbitrary queries.

Recall that for an arbitrary query Q , we define two different types of vertexes: a set of core vertices U_c and a set of satellite vertices U_s . The QUERYDECOMPOSE procedure in Line 1 of Algorithm 3, performs this decomposition by splitting the query vertices U into U_c and U_s , as observed in Figure 4.

To process arbitrary query multigraphs, we perform recursive sub-multigraph matching procedure on the set of core vertices $U_c \subseteq U$; during the recursion, satellite vertexes connected to a specific core vertex are processed too. Since the recursion is performed on the set of core vertices, we propose a few heuristics for ordering the query vertices.

Ordering of the query vertices forms one of the vital steps for subgraph matching algorithms [11]. In any subgraph matching algorithm, the embeddings of a query subgraph are obtained by exploring the solution space spanned by the data graph. But since the solution space itself can grow exponentially in size, we are compelled to use intelligent strategies to traverse the solution space. In order to achieve this, we propose a heuristic procedure VERTEXORDERING (Line 2, Algorithm 3) that employs two ranking functions.

The first ranking function r_1 relies on the number of satellite vertices connected to the core vertex, and the query vertices are ordered with the decreasing rank value. Formally, $r_1(u) = |U_{sat}|$, where $U_{sat} = \{u_s | u_s \in U_s \wedge (u, u_s) \in E(Q)\}$. A vertex with more satellite vertices connected to it, is rich in structure and hence it would probably yield fewer candidate solutions to be processed under recursion. Thus, in Figure 4, u_1 is chosen as an initial vertex. The second ranking function r_2 relies on the number of incident edges on a query vertex. Formally, $r_2(u) = \sum_{j=1}^m |\sigma(u)^j|$, where u

has m multiedges and $|\sigma(u)^j|$ captures the number of edge types in the j^{th} multiedge. Again, U_c^{ord} contains the ordered vertices with the decreasing rank value r_2 . Further, when there are no satellite vertices in the query Q , this ranking function gets the priority. Despite the usage of any ranking function, the query vertices in U_c^{ord} , when accessed in sequence, should be structurally connected to the previous set of vertices. If two vertices tie up with the same rank, the rank with lesser priority determines which vertex wins. Thus, for the example in Figure 4, the set of ordered core vertices is $U_c^{ord} = \{u_1, u_3, u_5\}$.

Algorithm 3: AMBER-ALGO (\mathcal{I}, Q)

```

1 QUERYDECOMPOSE: Split  $U$  into  $U_c$  and  $U_s$ 
2  $U_c^{ord} = \text{VERTEXORDERING}(Q, U_c)$ 
3  $u_{init} = u | u \in U_c^{ord}$ 
4  $CandInit = \text{QUERYSYNINDEX}(u_{init}, S)$ 
5  $CandInit = CandInit \cap \text{PROCESSVERTEX}(u_{init}, Q, \mathcal{A}, \mathcal{N})$ 
6 FETCH:  $U_{init}^{sat} = \{u | u \in U_s \wedge (u_{init}, u) \in E(Q)\}$ 
7 SET:  $Emb = \emptyset$ 
8 for  $v_{init} \in CandInit$  do
9   SET:  $M = \emptyset, M_s = \emptyset, M_c = \emptyset$ 
10  if  $U_{init}^{sat} \neq \emptyset$  then
11     $M_{sat} = \text{MATCHSATVERTICES}(\mathcal{A}, \mathcal{N}, Q, U_{init}^{sat}, v_{init})$ 
12    if  $M_{sat} \neq \emptyset$  then
13      for  $[u_s, V_s] \in M_{sat}$  do
14        UPDATE:  $M_s = M_s \cup [u_s, V_s]$ 
15        UPDATE:  $M_c = M_c \cup [u_{init}, v_{init}]$ 
16         $Emb = Emb \cup \text{HOMOMORPHICMATCH}(M, \mathcal{I}, Q, U_c^{ord})$ 
17  else
18    UPDATE:  $M_c = M_c \cup (u_{init}, v_{init})$ 
19     $Emb = Emb \cup \text{HOMOMORPHICMATCH}(M, \mathcal{I}, Q, U_c^{ord})$ 
20 return  $Emb$  /* Homomorphic embeddings of query multigraph */

```

The first vertex in the set U_c^{ord} is chosen as the initial vertex u_{init} (Line 3), and subsequent query vertices are chosen in sequence. The candidate solutions for the initial query vertex $CandInit$ are returned by QUERYSYNINDEX procedure (Line 4), that are constrained by the structural properties (neighbourhood structure) of u_{init} . By querying the index S for initial query vertex u_{init} , we obtain the candidate solutions $CandInit \in V$ that match the structure (multiedge types) associated with u_{init} . Although some candidates in $CandInit$ may be invalid, all valid candidates are present in $CandInit$, as deduced in Lemma 1. Further, PROCESSVERTEX procedure is invoked to obtain the candidate solutions according to vertex attributes and IRI information, and then only the common candidates are retained.

Before getting into the algorithmic details, we explain how the solutions are handled and how we process each query vertex. We define M as a set of tuples, whose i^{th} tuple is represented as $M_i = [m_c, M_s]$, where m_c is a solution pair for a core vertex, and M_s is a set of solution pairs for the set of satellite vertices that are connected to the core vertex. Formally $m_c = (u_c, v_c)$, where u_c is the core vertex and v_c is the corresponding matched vertex; M_s is a set of solution pairs, whose j^{th} element is a solution pair (u_s, V_s) , where u_s is a satellite vertex and V_s is a set of matched vertices. In addition, we maintain a set M_c whose elements are the solution pairs for all the core vertices. Thus during each recursion branch, the size of M grows until it reaches the query size $|U|$; once $|M| = |U|$, homomorphic matches are obtained.

For all the candidate solutions of initial vertex $CandInit$,

we perform recursion to obtain homomorphic embeddings (lines 8-19). Before getting into recursion, for each initial match $v_{init} \in CandInit$, if it has satellite vertices connected to it, we invoke the MATCHSATVERTICES procedure (Lines 10-11). This step not only finds solution matches for satellite vertices, if there are, but also checks if v_{init} is a valid candidate vertex. If the returned solution set M_{sat} is empty, then v_{init} is not a valid candidate and hence we continue with the next $v_{init} \in CandInit$; else, we update the set of solution pairs M_s for satellite vertices and the solution pair M_c for the core vertex (Lines 12-15) and invoke HOMOMORPHICMATCH procedure (Lines 17). On the other hand, if there are no satellite vertices connected to u_{init} , we update the core vertex solution set M_c and invoke HOMOMORPHICMATCH procedure (Lines 18-19).

Algorithm 4: HOMOMORPHICMATCH($M, \mathcal{I}, Q, U_c^{ord}$)

```

1 if  $|M| = |U|$  then
2   return GENEMB( $M$ )
3  $Emb = \emptyset$ 
4 FETCH:  $u_{next} = u | u \in U_c^{ord}$ 
5  $N_q = \{u_c | u_c \in M_c\} \cap adj(u_{next})$ 
6  $N_g = \{v_c | v_c \in M_c \wedge (u_c, v_c) \in E_c\}$ , where  $u_c \in N_q$ 
7  $Cand_{u_{next}} = \bigcap_{n=1}^{|N_q|} (QueryNeighIndex(\mathcal{N}, L_E^Q(u_n, u_{next}), v_n))$ 
8  $Cand_{u_{next}} = Cand_{u_{next}} \cap PROCESSVERTEX(u_{next}, Q, \mathcal{A}, \mathcal{N})$ 
9 for each  $v_{next} \in Cand_{u_{next}}$  do
10  FETCH:  $U_{next}^{sat} = \{u | u \in V_s \wedge (u_{next}, u) \in E(Q)\}$ 
11  if  $U_{next}^{sat} \neq \emptyset$  then
12     $M_{sat} = MATCHSATVERTICES(\mathcal{A}, \mathcal{N}, Q, U_{next}^{sat}, v_{next})$ 
13    if  $M_{sat} \neq \emptyset$  then
14      for every  $[u^s, V^s] \in M_{sat}$  do
15        UPDATE:  $M_s = M_s \cup [u^s, V^s]$ 
16        UPDATE:  $M_c = M_c \cup (u_{next}, v_{next})$ 
17         $Emb = Emb \cup HOMOMORPHICMATCH(M, \mathcal{I}, Q, U_c^{ord})$ 
18  else
19    UPDATE:  $M_c = M_c \cup (u_{next}, v_{next})$ 
20     $Emb = Emb \cup HOMOMORPHICMATCH(M, \mathcal{I}, Q, U_c^{ord})$ 
21 return  $Emb$ 

```

In the HOMOMORPHICMATCH procedure (Algorithm 4), we fetch the next query vertex from the set of ordered core vertices U_c^{ord} (Line 4). Then we collect the neighbourhood vertices of already matched core query vertices and the corresponding matched data vertices (Lines 5-6). As we recall, the set M_c maintains the solution pair $m_c = (u_c, v_c)$ of each matched core query vertex. The set N_q collects the already matched core vertices $u_c \in M_c$ that are also in the neighbourhood of u_{next} , whose matches have to be found. Further, N_g contains the corresponding matched query vertices $v_c \in M_c$. As the recursion proceeds, we find those matchable data vertices of u_{next} that are in the neighbourhood of all the matched vertices $v \in N_g$, so that the query structure is maintained. In Line 7, for each $u_n \in N_q$ and the corresponding $v_n \in N_g$, we query the neighbourhood index \mathcal{N} , to obtain the candidate solutions $Cand_{u_{next}}$, that are in the neighbourhood of already matched data vertex v_n and have the multiedge $L_E^Q(u_n, u_{next})$, obtained from the query multigraph Q . Finally (line 7), the set of candidate solutions that are common for every $u_n \in N_q$ are retained in $Cand_{u_{next}}$.

Further, the candidate solutions are refined with the help of PROCESSVERTEX procedure (Line 8). Now, for each of the valid candidate solution $v_{next} \in Cand_{u_{next}}$, we recursively call the HOMOMORPHICMATCH procedure. When the next query vertex u_{next} has no satellite vertices attached to it, we update

the core vertex solution set M_c and call the recursion procedure (Lines 19-20). But when u_{next} has satellite vertices attached to it, we obtain the candidate matches for all the satellite vertices by invoking the MATCHSATVERTICES procedure (Lines 11-12); if there are matches, we update both the satellite vertex solution M_s and the core vertex solution M_c , and invoke the recursion procedure (Line 17).

Once all the query vertices have been matched for the current recursion step, the solution set M contains the solutions for both core and satellite vertices. Thus when all the query vertices have been matched, we invoke the GENEMB function (Line 2) which returns the set of embeddings, that are updated in Emb . The GENEMB function treats the solution vertex v_c of each core vertex as a singleton and performs Cartesian product among all the core vertex singletons and satellite vertex sets. Formally, $Emb_{part} = \{v_c^1\} \times \dots \times \{v_c^{|U_c|}\} \times V_s^1 \times \dots \times V_c^{|U_s|}$. Thus, the partial set of embeddings Emb_{part} is added to the final result Emb .

6. RELATED WORK

The proliferation of semantic web technologies has influenced the popularity of RDF as a standard to represent and share knowledge bases. In order to efficiently answer SPARQL queries, many stores and API inspired by relational model were proposed [7, 3, 13, 5]. x-RDF-3X [13], inspired by modern RDBMS, represent RDF triples as a big three-attribute table. The RDF query processing is boosted using an exhaustive indexing schema coupled with statistics over the data. Also Virtuoso[7] heavily exploits RDBMS mechanism in order to answer SPARQL queries. Virtuoso is a column-store based systems that employs sorted multi-column column-wise compressed projections. Also these systems build table indexing using standard B-trees. Jena [5] supplies API for manipulating RDF graphs. Jena exploits multiple-property tables that permit multiple views of graphs and vertices which can be used simultaneously.

Recently, the database community has started to investigate RDF stores based on graph data management techniques [6, 16, 11]. The work in [6] addresses the problem of supporting property graphs as RDF, since majority of the graph databases are based on property graph model. The authors introduce a property graph to RDF transformation scheme and propose three models to address the challenge of representing the key/value properties of property graph edges in RDF. gStore [16] applies graph pattern matching techniques using filter-and-refinement strategy to answer SPARQL queries. It employs an indexing schema, named VS*-tree, to concisely represent the RDF graph. Once the index is built, it is used to find promising subgraphs that match the query. Finally, exact subgraphs are enumerated in the refinement step. Turbo_Hom++ [11] is an adaptation of a state of the art subgraph isomorphism algorithm (Turbo_ISO[9]) to the problem of SPARQL queries. Exploiting the standard graph isomorphism problem, the authors relax the injectivity constraint to handle the graph homomorphism, which is the RDF pattern matching semantics.

Unlike our approach, Turbo_Hom++ does not index the RDF graph, while gStore concisely represents RDF data through VS*-tree. Another difference between AMBER and the other graph stores is that our approach explicitly manages the multigraph induced by the SPARQL queries while no clear discussion is supplied for the other tools.

7. EXPERIMENTAL ANALYSIS

In this section, we perform extensive experiments on the three RDF benchmarks. We evaluate the time performance and the robustness of AMBER w.r.t. state-of-the-art competitors by varying the size, and the structure of the SPARQL queries. Experiments are carried out on a 64-bit Intel Core i7-4900MQ @ 2.80GHz, with 32GB memory, running Linux OS - Ubuntu 14.04 LTS. AMBER is implemented in C++.

7.1 Experimental Setup

We compare AMBER with the four standard RDF engines: *Virtuoso-7.1* [7], *x-RDF-3X* [13], *Apache Jena* [5] and *gStore* [16]. For all the competitors we employ the source code available on the web site or obtained by the authors. Another recent work *TurboHOM++* [11] has been excluded since it is not publicly available.

For the experimental analysis we use three RDF datasets - *DBPEDIA*, *YAGO* and *LUBM*. *DBPEDIA* constitutes the most important knowledge base for the Semantic Web community. Most of the data available in this dataset comes from the Wikipedia Infobox. *YAGO* is a real world dataset built from factual information coming from *Wikipedia* and *WordNet* semantic network. *LUBM* provides a standard RDF benchmark to test the overall behaviour of engines. Using the data generator we create *LUBM100* where the number represents the scaling factor.

Dataset	# Triples	# Vertices	# Edges	# Edge types
<i>DBPEDIA</i>	33 071 359	4 983 349	14 992 982	676
<i>YAGO</i>	35 543 536	3 160 832	10 683 425	44
<i>LUBM100</i>	13 824 437	2 179 780	8 952 366	13

Table 4: Benchmark Statistics

The data characteristics are summarized in Table 4. We can observe that the benchmarks have different characteristics in terms of number of vertices, number of edges, and number of distinct predicates. For instance, *DBPEDIA* has more diversity in terms of predicates (~ 700) while *LUBM100* contains only 13 different predicates.

The time required to build the multigraph database as well as to construct the indexes are reported in Table 5. We can note that the database building time and the corresponding size are proportional to the number of triples. Regarding the indexing structures, we can underline that both building time and size are proportional to the number of edges. For instance, *DBPEDIA* has the biggest number of edges ($\sim 15M$) and, consequently, AMBER employs more time and space to build and store its data structure.

Dataset	Database		Index \mathcal{I}	
	Building Time	Size	Building Time	Size
<i>DBPEDIA</i>	307	1300	45.18	1573
<i>YAGO</i>	379	2400	29.1	1322
<i>LUBM100</i>	67	497	18.4	1057

Table 5: Offline stage: Database and Index Construction time (in seconds) and memory usage (in Mbytes)

7.2 Workload Generation

In order to test the scalability and the robustness of the different RDF engines, we generate the query workloads considering a similar setting as in [8, 1, 9]. We generate the query workload from the respective RDF datasets, which are available as RDF tripleset. In specific, we generate two types of query sets: a star-shaped and a complex-shaped query set; further, both query sets are generated for varying sizes (say k) ranging from 10 to 50 triplets, in steps of 10.

To generate star-shaped or complex-shaped queries of size k , we pick an initial-entity at random from the RDF data. Now to generate star queries, we check if the initial-entity is present in at least k triples in the entire benchmark, to verify if the initial-entity has k neighbours. If so, we choose those k triples at random; thus the initial entity forms the central vertex of the star structure and the rest of the entities form the remaining star structure, connected by the respective predicates. To generate complex-shaped queries of size k , we navigate in the neighbourhood of the initial-entity through the predicate links until we reach size k . In both query types, we inject some object literals as well as constant *IRIs*; rest of the *IRIs* (subjects or objects) are treated as variables. However, this strategy could choose some very unselective queries [8]. In order to address this issue, we set a maximum time constraint of 60 seconds for each query. If the query is not answered in time, it is not considered for the final average (similar procedure is usually employed for graph query matching [9] and RDF workload evaluation [1]). We report the average query time and, also, the percentage of unanswered queries (considering the given time constraint) to study the robustness of the approaches.

7.3 Comparison with RDF Engines

In this section we report and discuss the results obtained by the different RDF engines. For each combination of query type and benchmark we report two plots by varying the query size: the average time and the corresponding percentage of unanswered queries for the given time constraint. We remind that the average time per approach is computed only on the set of queries that were answered.

The experimental results for *DBPEDIA* are depicted in Figure 6 and Figure 7. The time performance (averaged over 200 queries) for *Star-Shaped* queries (Fig. 6a), affirm that AMBER clearly outperforms all the competitors. Further the robustness of each approach, evaluated in terms of percentage of unanswered queries within the stipulated time, is shown in Figure 6b. For the given time constraint, *x-RDF-3X* and *Jena* are unable to output results for size 20 and 30 onwards respectively. Although *Virtuoso* and *gStore* output results until query size 50, their time performance is still poor. However, as the query size increases, the percentage of unanswered queries for both *Virtuoso* and *gStore* keeps on increasing from $\sim 0\%$ to 65% and $\sim 45\%$ to 95% respectively. On the other hand AMBER answers $>98\%$ of the queries, even for queries of size 50, establishing its robustness.

Analyzing the results for *Complex-Shaped* queries (Fig. 7), we underline that AMBER still outperforms all the competitors for all sizes. In Figure 7a, we observe that *x-RDF-3X* and *Jena* are the slowest engines; *Virtuoso* and *gStore* perform better than them but nowhere close to AMBER. We further observe that *x-RDF-3X* and *Jena* are the least robust as they don't output results for size 30 onwards (Fig. 7b);

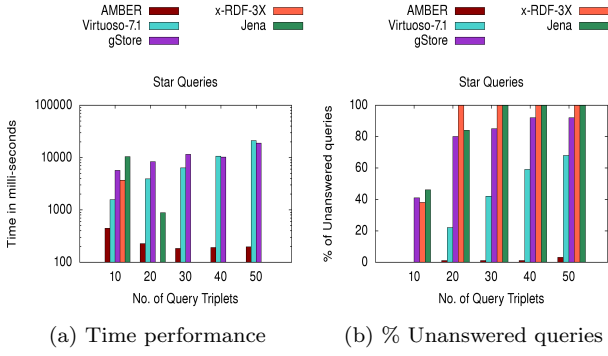

Figure 6: Evaluation of (a) time performance and (b) robustness, for *Star-Shaped* queries on *DBPEDIA*.

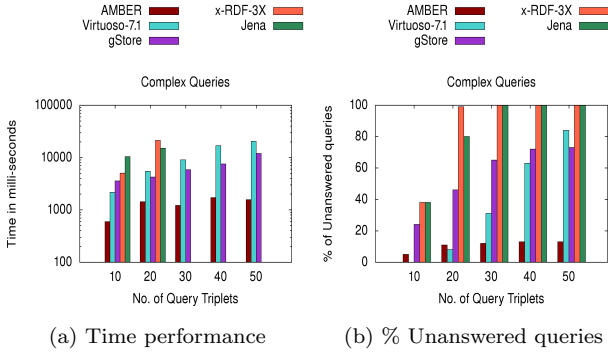

Figure 7: Evaluation of (a) time performance and (b) robustness, for *Complex-Shaped* queries on *DBPEDIA*.

on the other hand AMBER is the most robust engine as it answers $>85\%$ of the queries even for size 50. The percentage of unanswered queries for *Virtuoso* and *gStore* increase from 0% to $\sim 80\%$ and 25% to $\sim 70\%$ respectively, as we increase the size from 10 to 50.

The results for *YAGO* are reported in Figure 8 and Figure 9. For the *Star-Shaped* queries (Fig. 8), we observe that AMBER outperforms all the other competitors for any size. Further, the time performance of AMBER is 1-2 order of magnitude better than its nearest competitor *Virtuoso* (Fig. 8a), and the performance remains stable even with increasing query size (Fig. 8b). *x-RDF-3X*, *Jena* are not able to output results for size 20 onwards. As observed for *DBPEDIA*, *Virtuoso* seems to become less robust with the increasing query size. For size 20-40, time performance of *gStore* seems better than *Virtuoso*; the reason seems to be the fewer queries that are being considered. Conversely, AMBER is able to supply answers most of the time ($>98\%$).

Coming to the results for *Complex-Shaped* queries (Fig. 9), we observe that AMBER is still the best in time performance; *Virtuoso* and *gStore* are the closest competitors. Only for size 10 and 20, *Virtuoso* seems robust than AMBER. *Jena*, *x-RDF-3X* do not answer queries for size 20 onwards, as seen in Figure 9b.

The results for *LUBM100* are reported in Figure 10 and Figure 11. For the *Star-Shaped* queries (Fig. 10), AMBER always outperforms all the other competitors for any size (Fig. 10a). Further, the time performance of AMBER is

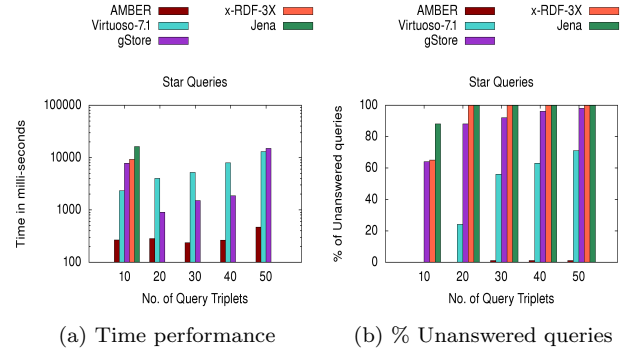

Figure 8: Evaluation of (a) time performance and (b) robustness, for *Star-Shaped* queries on *YAGO*.

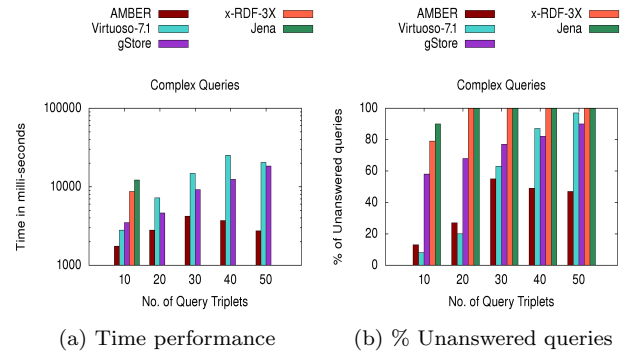

Figure 9: Evaluation of (a) time performance and (b) robustness, for *Complex-Shaped* queries on *YAGO*.

2-3 orders of magnitude better than its closest competitor *Virtuoso*. Similar to the *YAGO* experiments, *x-RDF-3X*, *Jena* are not able to manage queries from size 20 onwards; the same trend is observed for *gStore* too. Further, *Virtuoso* always loses its robustness as the query size increases. On the other hand, AMBER answers queries for all sizes.

Considering the results for *Complex-Shaped* queries (Fig. 11), we underline that AMBER has better time performance as seen in Figure 11a. *x-RDF-3X*, *Jena* and *gStore* did not supply answer for size 30 onwards (Fig. 11b). Further, *Virtuoso* seems to be a tough competitor for AMBER in terms of robustness for size 10 and 20. However, for size 30 onwards AMBER is more robust.

To summarise, we observe that *Virtuoso* is enough robust for *Complex-Shaped* smaller queries (10-20), but fails for bigger (>20) queries. *x-RDF-3X* fails for queries with size bigger than 10. *Jena* has reasonable behavior until size 20, but fails to deliver from size 30 onwards. *gStore* has a reasonable behavior for size 10, but its robustness deteriorates from size 20 onwards. To summarize, AMBER clearly outperforms, in terms of time and robustness, the state-of-the-art RDF engines on the evaluated benchmarks and query configuration. Our proposal also scales up better than all the competitors as the size of the queries increases.

8. CONCLUSION

In this paper, a multigraph based engine AMBER has

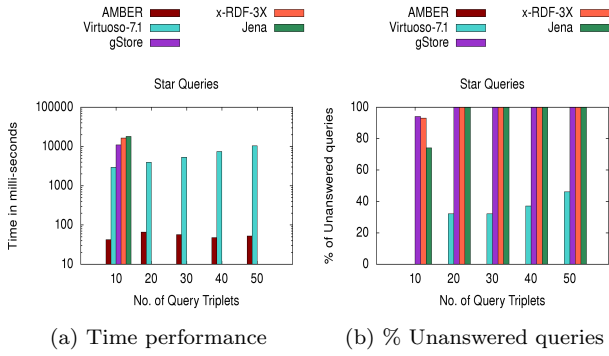

Figure 10: Evaluation of (a) time performance and (b) robustness, for *Star-Shaped* queries on *LUBM100*.

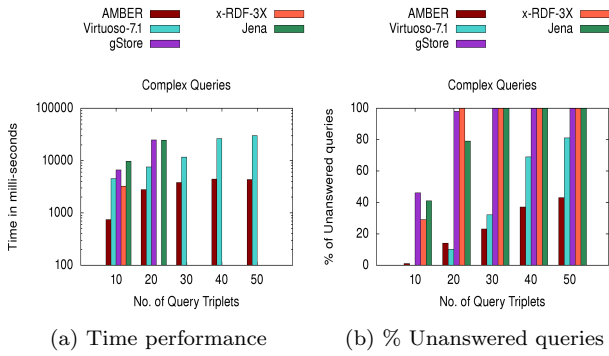

Figure 11: Evaluation of (a) time performance and (b) robustness, for *Complex-Shaped* queries on *LUBM100*.

been proposed in order to answer complex SPARQL queries over RDF data. The multigraph representation has bestowed us with two advantages: on one hand, it enables us to construct efficient indexing structures, that ameliorate the time performance of AMBER; on the other hand, the graph representation itself motivates us to exploit the valuable work done until now in the graph data management field. Thus, AMBER meticulously exploits the indexing structures to address the problem of sub-multigraph homomorphism, which in turn yields the solutions for SPARQL queries. The proposed engine AMBER has been extensively tested on three well established RDF benchmarks. As a result, AMBER stands out w.r.t. the state-of-the-art RDF management systems considering both the robustness regarding the percentage of answered queries and the time performance. As a future work, we plan to extend AMBER by incorporating other SPARQL operations and, successively, study and develop a parallel processing version of our proposal to scale up over huge RDF data.

ABSTRACT

Analytical queries are crucial for many emerging Semantic Web applications such as clinical-trial recruiting in Life Sciences that incorporate patient and drug profile data. Such queries compare aggregates over multiple groupings of data which pose challenges in expression and optimization of complex grouping-aggregation constraints. While these challenges have been addressed in relational models, the semi-structured nature of RDF introduces additional challenges that need further investigation. Each grouping required in an RDF analytical query maps to a graph pattern subquery with related groups leading to overlapping graph patterns within the same query. The resulting algebraic expressions for such queries contain large numbers of joins, groupings and aggregations, posing significant challenges for present-day optimizers.

In this paper, we propose an approach for supporting efficient and scalable RDF analytics that follows the well known technique of simplifying algebraic expressions of RDF analytical queries in a way that enables better optimization. Specifically, the approach is based on a refactoring of analytical queries expressed in the relational-like SPARQL algebra based on a new set of logical operators. This refactoring achieves shared execution of common subexpressions that enables parallel evaluation of groupings as well as aggregations, leading to reduced I/O and processing costs, particularly beneficial for scale-out processing on distributed Cloud systems. Experiments on real-world and synthetic benchmarks confirm that such a rewriting can achieve up to 10X speedup over relational-style SPARQL query plans executed on popular Cloud systems.

1. INTRODUCTION

Growing amount of linked open data is enabling interesting applications that combine data from different domains for analysis. For example, the ReDD-Observatory [38] discusses a study reporting the total number of deaths and the number of clinical trials for Tuberculosis and HIV/AIDS in all countries, to analyze the dispar-

ity between biomedical research and the disease burden in developing countries. This study involved information about clinical trials and effectiveness of treatment options from *ClinicalTrials.gov*, statistics about mortality for different countries from the *Global Health Observatory* (GHO), published by the World Health Organization and biomedical research (MEDLINE publications and other life science journals) available in the *PubMed*. The results need to be grouped based on both country and disease, followed by aggregations on the number of clinical trials and deaths due to the concerned disease in each country, using the grouping-aggregation constructs in SPARQL 1.1 [22]. Another Semantic Web application, AlzPharm [26], queries several semantically-linked neuroscience datasets to find information relevant to neurodegenerative diseases, e.g., identify the different groups of drugs used for Alzheimer's Disease when grouped by their molecular targets and clinical usage.

Non-trivial analytical queries require multiple aggregations over different groupings of data, some of which may be related, resulting

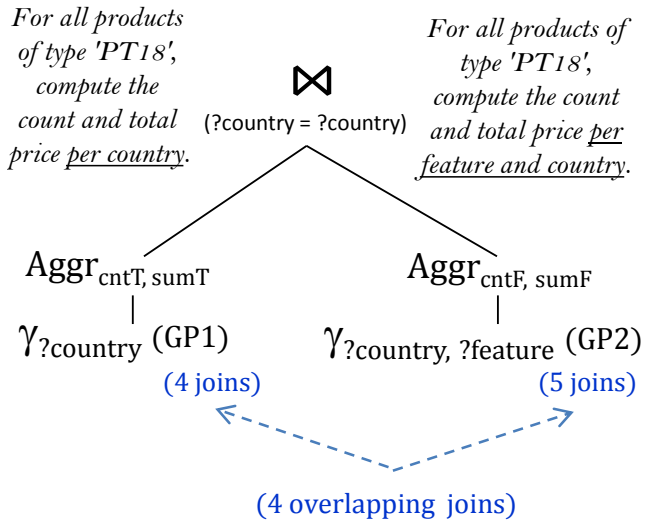

Figure 2: A relational-algebra based query plan for AQ1

in redundant scans and joins over large relations. Consider an example SPARQL analytical query *AQ1* shown in Figure 1, adopted from the Berlin SPARQL BI benchmark [1]. The query involves two descriptions GP1 and GP2 for products of type ‘PT18’ with grouping constraints on country and (country, feature) combinations, respectively. Each grouping constraint is defined over a graph pattern (a combination of one or more triple patterns¹ that specifies constraints to retrieve relevant subgraphs). Queries with multiple groupings involve multiple graph patterns. Further, if the groupings are related then there is a significant amount of overlap in the graph pattern subqueries. Figure 2 shows a summarized query plan with two major subqueries using the traditional evaluation technique: a subquery for GP1 with four joins that matches subgraphs about offers for products of type PT18, their price and vendor information, followed by a grouping on vendor’s country. The second subquery contains a similar graph pattern GP2 with five joins (an extra join due to the addition of product feature) followed by a grouping on country-feature. Answers from the two subqueries are then joined to compute the final price ratio, resulting in a total of 10 joins and 2 grouping operations.

In contrast, in the relational model, such OLAP queries are evaluated over suitably organized (star or snowflake) schemas consisting of n-ary relations. Different optimization strategies ranging from specialized query constructs [20, 9, 10], efficient indexing [31, 37], materialized views [21, 12], and efficient evaluation in distributed data warehouses [7, 6] have been proposed. In the absence of such schema organizations for RDF, a naive approach is to decompose the evaluation into two distinct phases: a graph pattern evaluation phase that constructs a suitable set of n-ary relations, followed by relational-style optimizations. However, such an approach prevents the possibility of optimizations across the two phases, e.g., early projections, partial aggregations, etc. Therefore, a holistic optimization strategy is likely to be more advantageous.

A promising direction is based on the observation made in [10] that relational expressions tightly couple grouping and aggregation specifications, often resulting in complex algebraic expressions that confound query optimizers. The approach in this paper has a similar spirit, i.e., grouping-aggregation specifications in RDF analyt-

ical queries are decoupled to optimize subqueries. Further, with a focus to support large scale RDF analytics, the paper overviews how such a query reformulation can be evaluated on Cloud platforms such as MapReduce [17]. The challenges with evaluating complex queries with many join operations have been addressed in several papers [4, 23, 33], and can be summarized as long, expensive execution workflows with multiple I/O and network data transfer phases. Many techniques have been proposed to mitigate these costs by sharing scans and computations [30, 28, 33] during MapReduce-based processing. In this paper, we present a holistic optimization that integrates the work on algebraic optimization of graph pattern queries with algebraic optimization of OLAP queries. Specifically, we make the following contributions:

- An algebraic rewriting of overlapping graph patterns (in a SPARQL analytical query) using a *composite graph pattern* based on common substructures. A decoupled reformulation of the grouping-aggregation definitions in a SPARQL analytical query expressed using a composite graph pattern.
- A set of logical and physical operators for efficient evaluation of a composite graph pattern, as well as parallel evaluation of independent aggregations on a composite graph pattern. The suite of operators and optimizations are integrated into *RAPIDAnalytics*, an extension of Apache Pig.
- A comprehensive evaluation of *RAPIDAnalytics* using basic and multi-aggregation SPARQL analytical queries on real-world as well as synthetic benchmark datasets.

The rest of the paper is organized as follows: Section 2 provides a background on complex OLAP queries and specific challenges in processing such queries over the RDF data model. Section 3 introduces an algebraic rewriting of SPARQL analytical queries based on a non-relational data model and algebra, followed by formal definitions of newly introduced logical operators. Section 4 describes the physical operators and optimizations to execute such a query plan on MapReduce-based platforms. Section 5 presents the comparative evaluation results between *RAPIDAnalytics* and other popular approaches, and Section 6 presents concluding remarks.

2. BACKGROUND AND CHALLENGES

2.1 Optimization of Complex OLAP Queries

There has been a body of work to enable better expression and evaluation [20, 19, 10, 6, 11] of complex OLAP queries including introduction of constructs such as the *CUBE BY* [20], grouping sets [9], etc., that allow the user to have a finer control over the grouping and aggregation specifications. An earlier work on *MD-Join* [10] showed that decoupling of the grouping definition and aggregation computations not only allows more succinct expression of complex OLAP queries, but can also eliminate redundant scans and joins over large fact tables.

Parallel / Distributed Evaluation of Relational OLAP Queries.

An earlier work on parallel evaluation of aggregates proposed adaptive algorithms [35] to handle a range of grouping selectivities (ratio of result size to input size) across queries. Subsequent research [6] on distributed evaluation of OLAP queries identified optimizations that exploit knowledge about data distributions to reduce the amount of data transfer between the local sites and the centralized coordinator. In the context of MapReduce, an overlapping redistribution scheme [14] was proposed to enable parallel evaluation of correlated aggregations with sliding windows. MR-Cube [29] distributes the cube computation of partially algebraic measures on MapReduce. It also introduced a value-partitioning scheme to deal with

¹RDF data is modeled as a set of triples = (Subject, Property, Object). A triple pattern is a triple with at least one variable denoted by a leading ‘?’

reducer-unfriendly (cube) groups that tend to increase the load on a reducer. The work on MR-Cube was integrated into Apache Pig² and Apache Hive³ (GROUPING SETS, CUBE and ROLLUP clauses). Such operations assume the existence of a fact relation on which CUBE and other operations can be applied, which does not hold true in the case of the RDF data model where triples are commonly represented as binary or ternary relations.

Expression and Evaluation of RDF Analytical Queries. The RDF Data Cube vocabulary (QB) [16] was provided as a recommendation to enable publication of statistical data in RDF adhering to Linked data principles. The work on Open Cubes vocabulary [18] enables representation of multidimensional data using RDF Schema (RDFS). Other extensions [24] propose a multi dimensional model based on QB to support OLAP queries, mapping them to SPARQL. Recent work on RDF analytics [15] proposed a way to define an analytical schema on RDF graphs and formalize analytical queries over such an analytical schema, by separating the grouping-aggregation definitions, similar to the relational *MD-Join* [10] operator. An earlier work [36] extended Pig’s query primitives to support MapReduce based execution of the *MD-Join* operator.

Discussion. The *MD-Join* approach to eliminate redundant scans and joins involving large fact relations, translates to reduction in I/O and network transfer costs in MapReduce-based processing of complex analytical queries. However, specifics of RDF analytics make it challenging to adopt such an approach. Unlike traditional OLAP systems where the fact and dimension tables are available and suitably organized into star or snowflake schema, the fine-grained data model in RDF necessitates several join operations to reassemble the relevant fact and dimension information, e.g., fact relation described by GP1 requires four join operations. A relational-style query plan that computes the detail relations described by GP1 and GP2, compiles into a lengthy MapReduce execution workflow with 9 map-reduce cycles (one per star-join). Such a sequential execution limits opportunities to share input scans in general. Furthermore, RDF analytical queries often involve (slightly) different join expressions for detail relations (refer to GP1 and GP2). Thus, in order to fully exploit the benefit of a decoupled reformulation using the *MD-Join* approach, we require additional optimizations that enable shared execution of the graph patterns in an RDF analytical query.

2.2 Shared Execution of Graph Pattern Queries

A commonly occurring pattern in OLAP queries involves comparing subtotals across multiple dimensions, which results in subqueries that compute groupings over an overlapping subset of dimensions, e.g., GP2 computes groupings on *country-feature*, while GP1 is a roll-up on ALL features. In the context of RDF, related groupings result in subqueries with common subexpressions (graph patterns with overlapping structure) enabling opportunities for shared execution. For example, if two graph patterns in a query have the same structure (same join expression), then the graph pattern can be evaluated only once. In cases where graph patterns have subsumption relationship in join expressions, there may be opportunities to rewrite the query in a way that allows shared execution of common substructures. Even with structurally different graph patterns, there may be sharing opportunities within a MapReduce cycle.

Several techniques have been proposed to enable sharing of scans and computations across a MapReduce workload in order to reduce the associated I/O and network transfer costs, e.g., MRShare [30]

proposes sharing of input scans, sharing map functions and map output, while executing a batch of grouping queries on a common input table. YSmart [28] groups correlated operations in complex queries, e.g., Joins and GROUP BYs accessing the same table, into a single MapReduce job to reduce redundant scans, computations, and network transfers (integrated into Hive 0.12.0).

A previous work [27] on multi-query optimization (MQO) of SPARQL queries, rewrites the input graph pattern queries into a set of queries Q_{OPT} using the SPARQL OPTIONAL⁴ clause. Given a set of graph pattern queries Q with common substructures, the basic idea of SPARQL MQO is to (i) rewrite the input queries into a set of queries Q_{OPT} with OPTIONAL clauses (representing non-overlapping structures), (ii) evaluate queries Q_{OPT} over the RDF graph, and (iii) distribute the results of Q_{OPT} to input queries in Q . For example, two queries with the following set of triple patterns:

$Q_1: (?s \text{ p1 } ?o)$

$Q_2: (?s1 \text{ p1 } ?o1) (?s1 \text{ p2 } ?o2)$

can be expressed using the OPTIONAL clause as follows:

$Q_{OPT}: (?s \text{ p1 } ?o) \text{ OPTIONAL } (?s \text{ p2 } ?o2)$

where the non-overlapping triple pattern in Q_2 is specified as optional, i.e., resulting tuples may have NULL values for bindings of second triple pattern. Results matching original queries are extracted from results of Q_{OPT} . Note that multi-valued properties in the optional component may introduce duplicity and require special handling.

Discussion. A possible strategy to optimize RDF analytical queries is to rewrite and evaluate the individual graph patterns using the SPARQL MQO approach, extract answers to original graph patterns, and compute groupings over extracted subquery results. While such a rewriting seems beneficial when compared to sequential evaluation of individual graph patterns on MapReduce, our experiments on Hive showed that evaluating Q_{OPT} ahead of time prevents optimizations such as early projection and partial aggregations. This is because Q_{OPT} would need to be evaluated and stored as an intermediate table, since Hive neither supports logical views involving complex queries with multiple joins, nor does it support materialized views.

2.3 Rationale of Our Approach

We argue that it is necessary to approach the problem of optimizing RDF analytics *holistically*, rather than a two-step approach of independently optimizing the graph pattern matching phase and the grouping-aggregation phases. Given that RDF analytical queries often involve repeated computations over slightly different graph patterns, query plans that enable shared execution of common subpatterns are likely to compile into efficient execution plans. An important factor in this regard is the choice of algebra, the associated data model and the set of operators. One may use a relational-like algebra or alternatives such as the Nested TripleGroup Data Model and Algebra (NTGA) [33, 25]. We chose to use NTGA due to its underlying “groups of triples” or *triplegroup* model that enables concurrent computation of star-shaped join subpatterns (star-joins) in a query. The NTGA query plans not only enable sharing of scans and computations across multiple star subpatterns (resulting in shortened map-reduce execution workflows), but also concisely represent intermediate results in a denormalized form. In the next section, we build on the foundations of sharing that is already inherent in the NTGA approach and enhance its benefits by optimizing complex grouping-aggregation constraints.

²<https://pig.apache.org/>

³<https://hive.apache.org/>

⁴The OPTIONAL clause is used in SPARQL to allow querying of predicates that may not exist, i.e., answer is returned if there is a subgraph matching the OPTIONAL graph pattern, else it is ignored.

$\text{role}(?v)$	Role of variable $?v$ (subject, property, or object)
$\text{prop}(tp)$	Property of triple pattern tp
$\text{props}(Stp_i)$	Set of properties in Stp_i
$\delta(?v)$	Variable substitution in a triple matching tp

3. ALGEBRAIC REWRITING OF SPARQL ANALYTICAL QUERIES

We reformulate SPARQL analytical queries with multiple grouping-aggregation constraints by, (i) identifying *overlaps* between graph patterns in a query based on structural constraints, (ii) evaluating a *composite graph pattern* that retrieves answers for original graph patterns, and (iii) computing required groupings and aggregations based on the composite graph pattern. Common notations and convenience functions used in this paper are summarized in Table 1.

Definition 3.1 (Overlapping Star Patterns) Let Stp_1 and Stp_2 be two subject-rooted star subpatterns and let L be the intersection of their property sets, i.e., $L = \text{props}(Stp_1) \cap \text{props}(Stp_2)$. Then, Stp_1 and Stp_2 are considered to overlap if the following holds:

- Intersection of their property sets is non-empty, i.e., $L \neq \emptyset$.

- For any triple pattern $tp_1 = (s1, \text{rdf:type}, o1) \in Stp_1$, there exists some $tp_2 = (s2, \text{rdf:type}, o2) \in Stp_2$, with the same object component, i.e., $o1 = o2$.

Figure 3 represents two analytical queries AQ2 and AQ3, each consisting of two graph patterns GP1 and GP2 (properties abbreviated). In the case of query AQ2, star pattern $Stp_a \in GP1$ overlaps with $Stp_\alpha \in GP2$ since both match on the object of rdf:type triple. Similarly, star patterns Stp_b and Stp_β overlap. The graph patterns in AQ4 also have two overlapping star patterns, i.e., Stp_c structurally overlaps with Stp_γ , and Stp_d overlaps with Stp_δ .

Additionally, analytical queries may contain `FILTER` clauses that need to be considered while determining overlap between star patterns. For example, consider a filter on GP1 to retrieve a subset of products with price (property abbreviated as `pc`) > 5000, i.e., `FILTER(?o5 > 5000)`. A possible strategy is to compute generalized composite star patterns (without filter) and apply restrictions prior to the aggregation phase. Pushing the filter to a later phase in the workflow may have implications on I/O and network transfer costs associated with materialization of some irrelevant intermediate results. Another interesting case is that of unbound-property star patterns containing triple patterns such as $(?s1 ?p o1)$, used to query unknown or don't care relationships. Such queries need special handling, specifically if the unbound-property triple pattern participates in a join with other star patterns. Advanced optimizations for both these cases are out of scope of this paper. For the rest of this paper, we consider optimization of multi-graph-pattern queries involving bound-property star patterns with same filter constraints or filter constraints on a non-intersecting property.

Next, we generalize the notion of overlap to graph patterns by capturing similarity of join structures between star patterns. In order to do so, we introduce the concept of *role-equivalence* of join variables. Given two triple patterns tp_1 and tp_2 , a join variable jv_1 is a variable in $\text{var}(tp_1) \cap \text{var}(tp_2)$. A join variable $jv_1 \in tp_1$ is said to be *role-equivalent* to join variable $jv_3 \in tp_3$ if, (i) the corresponding triple patterns agree on the property component, i.e., $\text{prop}(tp_1) = \text{prop}(tp_3)$, and (ii) the join variables play the same role (subject, property, or object), i.e., $\text{role}(jv_1)$ in tp_1 is the same as $\text{role}(jv_3)$ in tp_3 .

Definition 3.2 (Overlapping Graph Patterns) Let graph pattern GP1 involve star subpatterns Stp_a, Stp_b, \dots , such that jv_{ab} de-

Figure 4: NTGA logical operators to evaluate composite graph patterns

notes the variable that joins a triple pattern $jtp_a \in Stp_a$ with $jtp_b \in Stp_b$. Let graph pattern GP2 involve star subpatterns $Stp_\alpha, Stp_\beta, \dots$ such that $jv_{\alpha\beta}$ denotes the variable that joins a triple pattern $jtp_\alpha \in Stp_\alpha$ with $jtp_\beta \in Stp_\beta$. Then, the graph patterns GP1 and GP2 are said to overlap if the following conditions hold:

- Each star pattern $Stp_a \in GP1$ overlaps with some star pattern $Stp_\alpha \in GP2$
- Given a pair of overlapping star patterns Stp_a and Stp_α , their join variables jv_{ab} and $jv_{\alpha\beta}$ are role-equivalent.

In the case of AQ2, graph patterns GP1 and GP2 overlap since both star patterns overlap and have the same join structure, e.g., subject-object join between Stp_a and Stp_b in GP1 matches the join structure between Stp_α and Stp_β in GP2. In the case of AQ3, both star patterns overlap. However, Stp_c joins Stp_a using an object-subject join, whereas Stp_γ joins Stp_δ using an object-object join. Since the join structures are not similar, we consider GP1 and GP2 to be non-overlapping. Though there may be possibilities to share some scans and computations across non-overlapping graph patterns, for the rest of the paper we consider optimization of overlapping graph patterns.

Construction of a Composite Graph Pattern. Overlapping graph patterns GP1 and GP2 can be re-written as a *composite graph pattern* GP' that captures the (non) overlapping substructures. For a pair of overlapping star patterns $Stp_a \in GP1$ and $Stp_\alpha \in GP2$, we define a composite star pattern Stp'_i such that:

- $\text{props}(Stp'_i) = P_{prim} \cup P_{sec}$
- $P_{prim} = \text{props}(Stp_a) \cap \text{props}(Stp_\alpha)$, set of *primary* properties defining common substructures across star patterns.
- $P_{sec} = \{ p_i \mid p_i \in \text{props}(Stp_a) \cup \text{props}(Stp_\alpha), p_i \notin P_{prim} \}$, set of *secondary* properties defining non-overlapping structures.

For example, $Stp_a \in GP1$ and $Stp_\alpha \in GP2$ can be rewritten as Stp'_a such that $\text{props}(Stp'_a) = \{ \text{ty18}, \underline{\text{pf}} \}$, where ty18 (short for rdf:type PT18) is the primary property and pf is the secondary property (underlined). Similarly, $Stp_b \in GP1$ and $Stp_\beta \in GP2$ can be expressed as Stp'_b with set of properties $\{ \text{pr}, \text{pc}, \underline{\text{ve}} \}$. Query AQ1 can be re-written using a composite graph pattern:

$$GP' = (Stp'_1 \bowtie Stp'_2 \bowtie Stp'_3)$$

where $\text{props}(Stp'_1) = \{ \text{ty18}, \underline{\text{pf}} \}$, $\text{props}(Stp'_2) = \{ \text{pr}, \text{pc}, \underline{\text{ve}} \}$, and $\text{props}(Stp'_3) = \{ \text{cn} \}$.

Answers matching a composite graph pattern may contain superfluous subtuples that do not match either of the original patterns, resulting in wrong aggregates. Hence, we need a way to validate join combinations.

An NTGA-based rewriting of a SPARQL analytical query requires support to compute and manipulate triplegroups that match composite star patterns and composite graph patterns. Specifically, we need support for the following operations – (i) A specialized triplegroup-filter operator that validates secondary (optional) properties in a composite star pattern; (ii) An operator to extract subsets of a triplegroup that match n original star patterns; (iii) A special join operator that restricts joins on valid combinations of composite star patterns; (iv) An operator in the spirit of *MD-Join* to compute grouping-aggregations on triplegroups. Next, we formally define the triplegroup-based logical operators. We assume our input to be a set of subject triplegroups (triples grouped on subject column).

3.1 Logical Operators

Definition 3.3 (Optional Group Filter) Given a set of subject triplegroups TG and a star pattern Stp containing a set of primary properties P_{prim} , and a set of optional properties P_{opt} , the **optional group-filter** operator $\sigma_{P_{prim}, P_{opt}}^{opt}$ returns the subset of triplegroups in TG that contains a non-empty subset of triples matching all properties in P_{prim} and may contain triples matching properties in P_{opt} . Specifically,

$$\sigma_{(P_{prim}, P_{opt})}^{opt}(TG) := \{ tg_i \in TG \mid P_{prim} \subseteq \text{props}(tg_i) \subseteq (P_{prim} \cup P_{opt}) \}$$

where $\text{props}(tg_i)$ returns the set of properties in a triplegroup tg_i . Essentially, $\sigma_{P_{prim}, P_{opt}}^{opt}$ ensures that triplegroups contain a matching triple for each of the primary properties and may contain matches for properties in P_{opt} . For example, given $P_{prim} = \{ \text{product}, \text{price} \}$, triplegroup tg_1 , tg_2 , and tg_4 are valid results for the $\sigma_{P_{prim}}^{opt}$ expression in Figure 4(a). However, tg_3 does not contain a matching triple for the primary property price, and hence gets filtered out. Note that valid triplegroups may have triples matching zero or more of the two optional properties $P_{opt} = \{ \text{validFrom}, \text{validTo} \}$.

Table 2: Evaluating composite graph patterns using α -Join

GP1	GP2	GP'	$\bowtie_{(\alpha_1 \vee \alpha_2)}^\gamma (...)$	
$Stp_1:Stp_2$	$Stp_1:Stp_2$	$Stp_1:Stp_2'$	α_1	α_2
ab:de	ab:de	ab:de	—	—
ab:de	ab:de	ab:de	$f = \emptyset$	$f \neq \emptyset$
ab:de	abc:de	abc:de	$c = \emptyset \wedge f = \emptyset$	$c \neq \emptyset \wedge f \neq \emptyset$
abc:de	ab:de	abc:de	$c \neq \emptyset \wedge f = \emptyset$	$c = \emptyset \wedge f \neq \emptyset$
abc:de	ab:de	abc:de	$c \neq \emptyset \wedge f = \emptyset$	$c = \emptyset \wedge f \neq \emptyset$
			$\wedge g = \emptyset$	$\wedge g \neq \emptyset$

Definition 3.4 (n-split) Given a set of triplegroups TG , a set of primary properties P_{prim} , and n sets of secondary properties $\{P_{sec_1}, P_{sec_2}, \dots, P_{sec_n}\}$, the **n-split** operator χ creates a set of n triplegroups as follows:

$$\chi(P_{prim}, \{P_{sec_1}, P_{sec_2}, \dots, P_{sec_n}\})(TG) := \{tg'_i, i \in [1, n]\}$$

such that:

- $tg'_i = tg_{prim} \cup tg_{sec_i}$, where $tg_{prim}, tg_{sec_i} \subseteq tg, tg \in TG$
- $props(tg_{prim}) = P_{prim}$ and $props(tg_{sec_i}) = P_{sec_i}$

The n-split operator extracts n subsets of a triplegroup based on n sets of secondary properties, one for each of the original star patterns. Figure 4(b) shows triplegroups resulting from an n-split operation on TG' ($n=2$), with $P_{prim} = \{\text{product, price}\}$, and two sets of secondary properties – $P_{sec_1} = \{\text{validFrom}\}$, and $P_{sec_2} = \{\text{validTo}\}$. While triplegroup tg_{41} conforms to the first pattern combination with properties $\{\text{product, price, validFrom}\}$, triplegroups tg_{12} and tg_{42} match the second combination $\{\text{product, price, validTo}\}$. Figure 4(c) shows another example of the n-split operation with $P_{sec_1} = \{\}$ and $P_{sec_2} = \{\text{validTo}\}$, i.e., the first combination contains only primary (no secondary) properties.

Let GP_{abcde} and GP_{abdef} be original graph patterns in a query and let Stp_{abc} and Stp_{def} be composite star patterns. The join ($Stp_{abc} \bowtie Stp_{def}$) may result in pattern combinations such as $abde$ that do not match either of the original patterns and should be avoided. We encode valid pattern combinations using α conditions, a set of structural constraints on a TG equivalence class based on its secondary properties. For example, to ensure pattern combinations $abcde$, triplegroups in TG_{abc} must contain at least one triple with property c , represented as a constraint $\alpha: c \neq \emptyset$, for brevity.

Definition 3.5 (α -Join) Let TG_x and TG_y be two triplegroup equivalence classes that join on variables lv_x and lv_y belonging to joining triple patterns tp_x and tp_y , resp. Let $\alpha_1, \alpha_2, \dots, \alpha_m$ be m conditions involving secondary properties in the equivalence classes. Then the α -Join operator $\bowtie_{\{\alpha_1 \vee \dots \vee \alpha_m\}}^\gamma$ creates a joined triplegroup involving $tg_x \in TG_x$ and $tg_y \in TG_y$ if the following holds:

- Triplegroup tg_x contains a matching triple for tp_x , and triplegroup tg_y contains a matching triple for tp_y , such that their variable substitutions match.
- tg_x and tg_y satisfy at least one of the α conditions.

Table 2 shows examples of graph patterns GP1 and GP2, their composite graph pattern GP', and α constraints for the α -Join operator. For example, conditions α_1 and α_2 in row (5) correspond to the original graph patterns $abcde$ and $abdefg$ respectively, hence avoiding materialization of triplegroups matching irrelevant patterns such as $abde$, $abdef$, $abdeg$, $abcdef$, $abcdefg$, etc.

$$\gamma^{AgJ}(TG_{base}, TG_{\{ty18, pf, pr, pc, ve, cn\}}, l, \theta, \alpha) = TG_{\{sumF, countF\}}$$

where $l = \{\text{SUM}(\text{?price}), \text{COUNT}(\text{?price})\}$ and $\alpha = \{pf \neq \emptyset\}$

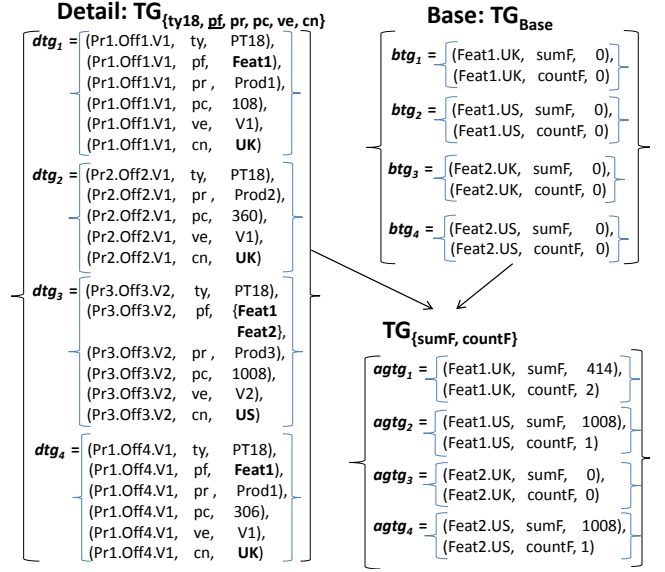

Figure 5: Example Triplegroup Agg-Join operation that computes groupings based on feature-country combination

Definition 3.6 (TG Agg-Join) Let TG_{base} and TG_{detail} be two triplegroup equivalence classes, θ be a condition involving variable substitutions in TG_{base} and TG_{detail} , and let l be a list of aggregation functions (f_1, f_2, \dots, f_m) over aggregation variables a_1, a_2, \dots, a_m , respectively. Let α be a condition involving one of the secondary properties in TG_{detail} . Then the triplegroup Agg-Join operator,

$$\gamma^{AgJ}(TG_{base}, TG_{detail}, l, \theta, \alpha)$$

creates a set of aggregated triplegroups ATG , where any aggregated triplegroup $agtgi \in ATG$ satisfies the following conditions:

- Each base triplegroup $btgi \in TG_{base}$ is associated with a set of triplegroups in TG_{detail} , using the following function :

$$RNG(btgi, TG_{detail}, \theta, \alpha) = \{dtg \in TG_{detail}\}$$

such that triplegroups $btgi$ and dtg satisfy conditions in θ and α .

- Then, for each base triplegroup $btgi \in TG_{base}$, an aggregated triplegroup $agtgi \in ATG$ is produced with triples $t_{ik} \in agtgi$ that contain values corresponding to some aggregation function f_k and variable a_k such that :

$$t_{ik} = (grpKey, createProp(f_k, a_k), f_k_agtgi_a_k)$$

whose values are computed as follows :

- $grpKey$ is the subject of $btgi$; $createProp(f_k, a_k)$ returns a unique property based on combination of aggregation function and variable.
- Aggregate $f_k_agtgi_a_k$ is computed by applying the function f_k on variable substitutions of a_k in triplegroups matching $RNG(btgi, TG_{detail}, \theta, \alpha)$.

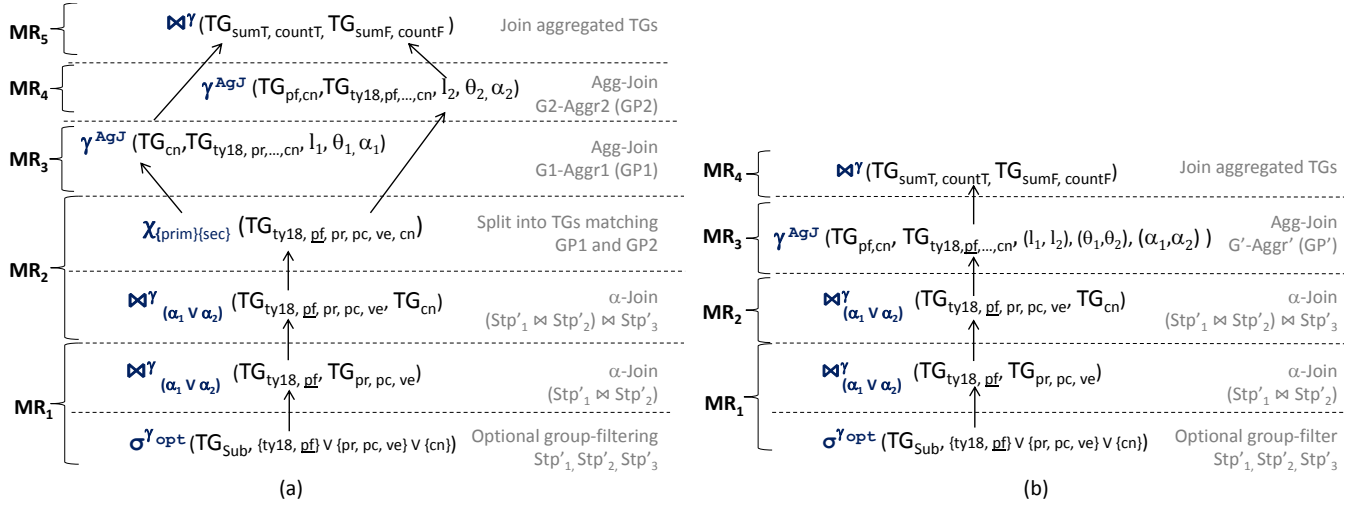

Figure 6: Translation to MapReduce execution workflows: (a) Sequential and (b) Parallel evaluation of aggregations on a composite graph pattern GP' . Properties: $ty18$ (rdf : type PT18), pf (productFeature), pr (product), pc (price), ve (vendor), cn (country)

A base triplegroup $btg_i \in TG_{base}$ corresponds to a distinct grouping key and produces an aggregated triplegroup $agt_i \in ATG$. Subset of triplegroups in TG_{detail} that contribute to an aggregated triplegroup agt_i is computed using function $RNG(btgi, TG_{detail}, \theta, \alpha)$, that returns the set of triplegroups in TG_{detail} that satisfy the join condition θ as well as the α condition with respect to the base triplegroup btg_i . The α condition defines restrictions based on secondary properties in TG_{detail} .

Figure 5 illustrates an example TG *Agg-Join* operation between TG equivalence classes TG_{base} (base) and $TG_{\{ty18, pf, pr, pc, ve, cn\}}$ (detail), to compute groupings based on feature and country. The RNG of a base triplegroup is calculated based on value bindings of the grouping variables $?feature$ and $?country$ in detail triplegroups (encoded as join condition θ). For triplegroup dtg_1 , bindings $\delta_1(?feature)=\{Feat1\}$ and $\delta_1(?country)=\{UK\}$. The α condition $pf \neq \emptyset$ ensures the presence of the secondary property pf (product feature). Triplegroup dtg_2 does not satisfy the α condition and hence does not contribute to any of the aggregated triplegroups. The RNG of base triplegroups is as follows:

$$\begin{aligned} RNG(btg_1, TG_{\{ty18, pf, pr, pc, ve, cn\}}, \theta, \alpha) &= \{ dtg_1, dtg_4 \} \\ RNG(btg_2, TG_{\{ty18, pf, pr, pc, ve, cn\}}, \theta, \alpha) &= \{ dtg_3 \} \\ RNG(btg_3, TG_{\{ty18, pf, pr, pc, ve, cn\}}, \theta, \alpha) &= \emptyset \\ RNG(btg_4, TG_{\{ty18, pf, pr, pc, ve, cn\}}, \theta, \alpha) &= \{ dtg_3 \} \end{aligned}$$

Given a base triplegroup btg_i , the aggregated triplegroup is computed by aggregating triplegroups in RNG of btg_i . For example, agt_1 is an aggregation of triplegroups dtg_1 and dtg_4 (RNG of btg_1). Note that RNG of btg_3 is empty and the aggregated triplegroup agt_3 retains default values.

4. QUERY EXECUTION ON MAPREDUCE

In MapReduce, data processing tasks (or queries) are encoded as a sequence of map-reduce function pairs which are executed in parallel on a cluster of machines. Extended MapReduce systems such as Apache Hive and Pig support high-level query primitives that are automatically compiled into a MapReduce execution workflow. The proposed logical operators were integrated into an NTGA-based extension of Apache Pig, called *RAPID+* [33, 25]. The extended system, called *RAPIDAnalytics*, includes pro-

posed optimizations to evaluate multi-aggregation SPARQL analytical queries. Both systems parse graph pattern queries in SPARQL and support a set of logical and physical operators for both Pig and NTGA. Interested readers can refer to [25] for architectural details of *RAPID+*.

4.1 Translation to MapReduce Plans

As with other relational-style Hadoop extensions, query compilation process in *RAPIDAnalytics* begins with a logical plan, which is compiled into a physical plan with physical operators. A physical operator is either a single function or a function pair that corresponds to map and reduce phases of the logical operator. For example, the optional group-filtering operator $TG_OptGrpFilter$ (σ^{opt}) is a single function and can be pipelined with other operators in either the map or the reduce phases. However, operators such as the triplegroup *Agg-Join* TG_AgJ which require redistribution of input, are defined as map-reduce function pairs. The assignment of the physical operators to MapReduce cycles constitutes a MapReduce plan.

Next, we summarize the execution workflow of our example query $AQ1$ on MapReduce. As described earlier, overlapping graph patterns $GP1$ and $GP2$ are re-written as a composite graph pattern:

$$GP': Stp_{ty18, pf} \bowtie Stp_{pr, pc, ve} \bowtie Stp_{cn}$$

Let TG_{Sub} be a set of subject triplegroups (set of triples grouped by Subject column). Figure 6(a) shows the query plan with the assignment of operators to map-reduce (MR) cycles. The optional group-filtering operator creates three sets of triplegroup equivalence classes – $TG_{\{ty18, pf\}}$, $TG_{\{pr, pc, ve\}}$, and $TG_{\{cn\}}$, that match the composite star patterns. The two α -Join operators compute the α -join between triplegroups to compute matches to the composite graph pattern. The n -split operator extracts matches to the original graph patterns $GP1$ and $GP2$. Subsequently, the two TG *Agg-Join* operators (γ^{AgJ}) compute the aggregations per country and per feature-country, resp. The final ratio is computed by joining the aggregated TG equivalence classes using a map-only phase.

An useful optimization [10, 5] is that a series of aggregations on the same detail relation can be evaluated in parallel if they are independent, i.e., the θ conditions of the second *Agg-Join* does not involve values generated by the first *Agg-Join*. Figure 6(b) shows the NTGA query plan and MapReduce execution plan that enables

parallel execution of the TG *Agg-Join* operator by combining them as a generalized operator (executed in MR cycle MR_3):

$$\gamma^{AgJ}(TG_{g1}, TG_{\{ty18, pf, pr, pc, ne, cn\}}, (l_1, l_2), (\theta_1, \theta_2), (\alpha_1, \alpha_2))$$

4.2 Algorithms for Physical Operators

Algorithm 1 gives an overview of the job flow for key phases in *RAPIDAnalytics* – *Job_i*, that computes the join between the triplegroup equivalence classes, and *Job_k*, that computes the aggregate join between the triplegroup equivalence classes. If there is a structural overlap in the input graph patterns, the triplegroup equivalence classes are computed based on the *composite* graph pattern. This is achieved by evaluating the optional group-filtering operator, *TG_OptGrpFilter*, based on the required and optional properties in the composite graph pattern. Below are map-reduce algorithms for the physical operators.

Algorithm 1: MR job workflow in *RAPIDAnalytics*

```
//Jobi:  $\alpha$ -Join between TG equivalence classes
Map:
   $TG' \leftarrow TG\_OptGrpFilter(TG, \langle EC, \{P_{prim}, P_{opt}\} \rangle);$ 
   $TG\_AlphaJoin(TG').Map();$ 
Reduce:
   $TG'' \leftarrow TG\_AlphaJoin(TG').Reduce();$ 
//Jobk: Agg-Join on TG equivalence classes
Map:
   $TG\_AgJ(TG'').Map();$ 
Reduce:
   $AggTG \leftarrow TG\_AgJ(TG'').Reduce();$ 
//Jobn: Join Aggregated TGs
Map:
   $TG\_Join(AggTG);$ 
```

TG_AlphaJoin: The input to this operator is a set of annotated triplegroups (matching a composite subpattern) whose join is to be computed. In order to eliminate pattern combinations that do not match any of the original graph patterns, all valid combinations are encoded as a list of α conditions, one for each of the original graph patterns. Algorithm 2 shows the map-reduce functions for the *TG_AlphaJoin* operator that integrates α -based filtering of irrelevant triplegroups during the join between equivalence classes.

In the map phase, an input triplegroup is tagged either on the *Subject* or *Object* value, based on the type of join. Each *reduce()* receives annotated triplegroups corresponding to the same join key. The algorithm iterates through triplegroups in the left equivalence class (*leftEC*) and right equivalence class (*rightEC*), and computes the join only if at least one of the α conditions is satisfied. For example, two triplegroups with properties *ab* and *de*, are not joined if the valid pattern combinations are *abcde* and *abdef*.

TG_AgJ: The input to this operator is a set of annotated triplegroups that match the composite graph pattern. The output is a set of aggregated triplegroups that contain the required aggregations. Algorithm 3 shows the map-reduce functions for the *TG_AgJ* operator. In order to reduce the number of intermediate triplegroups that are shuffled to the reducers, we implement a hash-based aggregation per mapper, i.e., instead of generating map output for each map input triplegroup, we partially aggregate the triplegroups at each mapper. The triplegroups are aggregated into a hashmap *multiAggMap* that is accessible across different map() invocations at a mapper. This hash-based aggregation resembles a local combiner within each mapper.

Each *Agg-Join agg* (identified by *id*) contains a θ condition, from which the grouping key *grp* is extracted. In the map phase,

Algorithm 2: TG_AlphaJoin (Triplegroup α -Join)

```
Map (key:null, val: AnnTG atg)
  if join on Subj then
    emit (atg.Sub, atg);
  else if join on Obj then
    objList  $\leftarrow$  extract objects corr. to join property from atg;
    foreach obj  $\in$  objList do
      emit (obj, atg);
Reduce (key:joinKey, val:List of AnnTGs TG') ;
   $\alphaList < \alpha_1, \dots, \alpha_n > \leftarrow \alpha$  restrictions for current join;
  leftList  $\leftarrow$  extract leftEC AnnTGs from TG';
  rightList  $\leftarrow$  extract rightEC AnnTGs from TG';
  foreach ltg  $\in$  leftList do
    foreach rtg  $\in$  rightList do
      if  $\exists \alpha \in \alphaList$  such that ltg and rtg satisfy  $\alpha$  then
        emit (joinTGs(ltg, rtg));
```

as each input triplegroup *atg* is processed, aggregations are computed if the α condition is satisfied. Once all aggregations for *agg* are computed, triplegroup *currAggTg* is aggregated with existing values in the mapper's global hashmap *multiAggMap*. Once the map() functions are complete, pre-aggregated entries in the global hashmap *multiAggMap* are output. Each reduce() receives pre-aggregated triplegroups corresponding to the same *id-grp* combination and further aggregates them.

Algorithm 3: TG_AgJ (Triplegroup Agg-Join)

```
Map (k:null, v: AnnTG atg)
  //Initialize multiAggMap for Map()
  //aggregation
  foreach agg  $< id, aggList, theta, alpha > \in aggList$  do
    if atg satisfies alpha then
      grp  $\leftarrow$  extract agg.theta from atg;
      curAggTg  $\leftarrow$  Aggregate atg based on aggList;
      Aggregate curAggTg to multiAggMap(k:id#grp);
Map.clean ()
  Emit pre-aggregated entries in multiAggMap;
Reduce (k:id#grp, v:List of AggTGs TG) ;
  grpAggTg  $\leftarrow$  Aggregate TG based on aggList;
  Emit aggregated triplegroup grpAggTg;
```

5. EMPIRICAL EVALUATION

This section presents a comprehensive evaluation of the proposed algebraic optimizations for RDF analytical queries. The performance of *RAPIDAnalytics* with two Hive approaches, (i) *Hive (Naive)*, SPARQL query translated into HiveQL, and (ii) *Hive (MQO)*, an MQO-based rewriting [27] of graph patterns using left outer joins, followed by a second HiveQL query to compute associated grouping and aggregations. Evaluation also included *RAPID+ (Naive)* [25], NTGA-based sequential evaluation of multiple graph patterns and grouping-aggregation phases.

5.1 Setup

Experiments were conducted on NCSU's VCL [34], where each node in the cluster was a dual core Intel X86 machine with 2.33GHz processor speed, 4GB memory, running Red Hat Linux. 10, 50, and 60-node Hadoop clusters (block size 128MB, 1GB heap-size for child jvms) were used with Hive release 0.12.0 and Hadoop 0.20.2.

Testbed - Dataset and Queries. Two synthetic datasets were generated by the Berlin SPARQL Benchmark (BSBM) [1] data

* No. of triple patterns in $Stp_1 : Stp_2 : \dots$

Figure 7: Evaluated RDF Analytical Queries

generator tool – *BSBM-500K* (43GB, 500K Products, ~175M triples) and *BSBM-2M* (172GB, 2M Products, ~700M triples). Evaluation of real-world RDF analytical queries was conducted on a chemogenomics RDF data warehouse, *Chem2Bio2RDF* [13], that is an aggregation of data from multiple chemical, biological, and chemogenomics data sources that link chemical compounds with targets, genes, side-effects, diseases, and publications (60GB, ~340M triples). Additional experiments were conducted on a second real-world dataset, *PubMed* (*Bio2RDF* release 2) [8] (230GB, ~1.7B triples).

The evaluation tested simple ($G1-G9$) as well as multi-grouping queries ($MG1-MG18$) with varying selectivities, varying granularity of groupings ($GROUP BY ALL$ vs. $GROUP BY feature$), and varying structures of associated graph patterns, as summarized in Figure 7. Queries $G1-G4$ and $MG1-MG4$ were adapted from the *BSBM Business Intelligence Use Case 3.1* [1], an e-commerce use case. Queries $G5-G9$ and $MG6-MG10$ were adapted based on case studies [13] on the *Chem2Bio2RDF* dataset, with use cases such as disease-specific drug discovery. Queries $MG11-MG18$ involve *PubMed* records. Additional details about all evaluated queries in SPARQL and Hive scripts are available on the project website [2].

Pre-processing. For Hive approaches, triples were vertically partitioned (VP) [3] and loaded into Hive tables with property-object partitions for *rdf:type* triples. All Hive tables were stored as *Optimized Row Columnar* (ORC)⁵ file format which aggressively compresses data (~80-96% reduction in data size with default compression) and has optimizations such as light-weight indexes to skip row groups for predicate-based filtering, column-level aggregates etc. For *RAPIDAnalytics* and *RAPID+*, triples were grouped on subject column to generate subject triplegroups, stored in text files based on equivalence class (set of properties). Further, *rdf:type* triples with *ProductType* objects were grouped based on prefixes to avoid creation of multiple small files. Additional details about the

⁵<https://cwiki.apache.org/confluence/display/Hive/LanguageManual+ORC>

pre-processing phase is available on the project website [2].

					G9	535	91

Table 3: Performance comparison of *Hive* and *RAPIDAnalytics* (R.A.) with varying structures of groupings (in seconds)

5.2 Evaluation Results

Varying Structure of Groupings. Four single-grouping queries were evaluated with varying selectivity of graph patterns and group granularity ($G1-G2$ with $GROUP BY ALL$ and $G3-G4$ with $GROUP BY feature$). Queries $G1$ and $G3$ pertain to *ProductType1* (low selectivity), while $G2$ and $G4$ pertain to *ProductType9* (high selectivity). Table 3 shows a performance comparison of *Hive* and *RAPIDAnalytics* for *BSBM-500K* (10-node cluster). *Hive* requires 4 MR cycles for all queries (MR_1-MR_2 for star patterns, MR_3 to join the stars, and MR_4 to compute grouping-aggregation). In cases where $(n-1)$ of the joining relations are small enough to fit in memory, *Hive* uses a map-join (map-only MR cycle), e.g., all subqueries involving *ProductType1* and *ProductType9*. Also *Hive* enables optimizations such as push down of *PROJECTS* and partial aggregation during preceding join operations. *RAPIDAnalytics* executes all four queries in 2 cycles (MR_1 for graph pattern processing and MR_2 for the *Agg-Join* operation), with a consistent performance gain of ~80% over *Hive* for all four queries.

Multiple Grouping-Aggregation Constraints. Figure 8(a-b) shows a performance comparison of all four approaches for queries $MG1-MG4$ with lo (low) and hi (high) query selectivity. Queries $MG1-MG2$ require 3 MR cycles per graph pattern in *Hive*, followed by 2 cycles for the grouping-aggregation (total 9 cycles). MQO-based *Hive* approach executes the composite graph pattern in 3 cycles, followed by 4 MR cycles to extract the distinct combinations matching the original patterns and compute the aggregations (total 7 cycles). *RAPID+* requires 2 MR cycles per subquery (1 MR for graph pattern matching, 1 MR for grouping-aggregation) and a map-only cycle to join the aggregated results (total 5 MR cycles). *RAPIDAnalytics* evaluated $MG1-MG2$ in 3 cycles (MR_1 to compute the composite graph pattern, MR_2 for parallel evaluation of the two grouping-aggregations and a map-only MR_3 to join the aggregated triplegroups).

Queries $MG3-MG4$ involve complex graph patterns with 3 star patterns. Sequential graph pattern processing in naive *Hive* results in a total of 11 MR cycles, while MQO-based *Hive* approach takes half the number of cycles for evaluating the composite graph pattern (8 MR cycles). *RAPID+* requires 2 MR cycles per graph pattern (7 MR cycles), while *RAPIDAnalytics* further reduces the number of cycles to 4 by parallel evaluation of the two grouping-aggregations. In general, the algebraic optimization in *RAPIDAnalytics* to group and aggregate on a composite graph pattern showed 30-45% gains over sequential evaluation of the different phases using naive *RAPID+*.

Scalability Study. Table 3 and Figure 8(b) show performance comparisons of 8 queries on a larger dataset *BSBM-2M*. The compression of input and intermediate results using the ORC File format, initializes less number of mappers (incur the overhead of decompression). *RAPID+* and *RAPIDAnalytics* initiate more number of mappers for most MR cycles leading to better utilization of re-

Figure 8: A performance comparison for multi-grouping SPARQL analytical queries

sources. For multi-grouping queries, *Hive (MQO)* did better than *Hive* for most cases with larger dataset due to higher savings in materialization of intermediate results, associated I/Os, and network transfers. *RAPIDAnalytics* showed 90-93% performance gains over *Hive (MQO)* for queries *MG1-MG2* on *BSBM-500K*, which further increased to 97% with *BSBM-2M*. Similar increase was seen for queries *MG3-MG4*, where performance gains of *RAPIDAnalytics* over *Hive (MQO)* increased from 78-81% to 93% with the larger setup.

Real-world RDF Analytics. Table 3 shows results for queries *G5-G9* on *Chem2Bio2RDF*. Query *G5* with 6 join operations was evaluated by *Hive* using map-only joins (due to small size VP tables). Similar optimizations were enabled by *Hive* for *G6-G8*, with clear benefits seen in the case of *G7*, where *RAPIDAnalytics* takes 12 additional seconds when compared to *Hive*. Query *G9* involves medline properties with large VP tables, forcing *Hive* to use full map-reduce cycles. *RAPIDAnalytics* shows 83% performance gain over *Hive* for *G9*. Figure 8(c) shows results for multi-aggregation queries, i.e., *MG6-MG8* with high selectivity (small VP relations), while queries *MG9-MG10* involve large VP relations. Naive *Hive* evaluates query *MG6* using 13 MR cycles (11 map-only), while MQO-based *Hive* approach requires 8 MR cycles (6 map-only). *RAPID+* evaluates *MG6* using 7 MR cycles (all map-reduce), with execution times almost comparable with *Hive (MQO)*. *RAPIDAnalytics* requires a total of 4 MR cycles. In general, even though the *Hive*-based approaches evaluate most of the joins in *MG6 – MG8* as map-joins, *RAPIDAnalytics* shows a performance gain of 40-50% over *Hive (MQO)* and 60% gains over naive *Hive* for queries *MG6-MG8*. In case of queries *MG9-MG10*, the findings are similar to BSBM datasets, with *RAPIDAnalytics* showing close to 90% performance gain over *Hive* approaches.

Results for the *Pubmed* dataset are summarized in Table 4. Queries *MG11 – MG12* and *MG17 – MG18* compute groupings over PubMed records, the associated grants, and the countries where the grants are issued. Queries *MG13-MG16* compute groupings based on publication type and authors of PubMed records and aggregate the number of Medical Subject (MeSH) Headings (query *MG13*) or associated chemicals (queries *MG14-MG16*). Further, selectivity of the queries were varied by querying different types of publications, e.g., *MG15* and *MG16* have similar query structure except that *MG15* retrieves PubMed records with publication type “Journal Article” while *MG16* concerns publications of type “News” (higher selectivity than journal article). Across all queries, *RAPIDAnalytics* showed improvements of above 93% over both *Hive* approaches. *Hive* performed the worst for queries

Query	PubMed (230GB dataset, 60-node cluster)			
	Hive (Naive)	Hive (MQO)	RAPID+ (Naive)	RAPID Analytics
MG11	2111	1753	229	124
MG12	2771	2898	229	126
MG13	120min*	15060	1102	651
MG14	18713	9124	756	462
MG15	13746	7320	619	338
MG16	10777	5795	464	237
MG17	2210	1851	226	118
MG18	5654	4817	306	202

* Eventually failed due to insufficient HDFS disk space.

Table 4: Evaluation of real-world queries on PubMed dataset (execution time in seconds)

MG13-MG16 that involve large VP relations (MeSH heading and chemical), due to the initiation of less number of mappers based on compressed (ORC) file sizes. Furthermore, while the *Hive MQO* approach eventually finished execution for query *MG13*, the naive *Hive* approach failed while computing the second graph pattern due to insufficient disk space. This is because one of the star-join cycles produces join output of size 190GB, which is materialized twice in the case of sequential execution of graph patterns, thus increasing the overall demand of required HDFS disk space. On the contrary, *RAPIDAnalytics* benefits from the concise representation of intermediate results using the NTGA approach while representing join results involving the multi-valued property MeSH heading. Further, the shared execution of graph patterns in *RAPIDAnalytics*, results in less number of materialization steps and less demand on required disk space. Overall, *RAPIDAnalytics* resulted in 40-48% performance gains over the sequential execution of graph patterns in *RAPID+*.

Discussion. Though *Hive(MQO)* compiles into a shorter execution workflow when compared to naive *Hive*, in some cases the performance is worse than sequential execution of subqueries. This is because of *Hive*’s lack of support for materialized views or views with complex join expressions, forcing the evaluation of the composite graph pattern as a separate *HiveQL* query. A direct implication of this is that optimizations based on the final query such as early projections and partial aggregations, which reduce the I/O and materialization in the intermediate phases, are not applicable. Another observation is that vertical-partitioning coupled with the ORC file format can be beneficial for queries that involve high-selectivity properties. Irrespective of the selectivity of the involved properties,

the algebraic optimization techniques in *RDFAnalytics* were found to be beneficial for multi-grouping queries by enabling shared execution of graph patterns as well as the required aggregations. *RAPIDAnalytics* can further benefit by integration of optimizations such as map-side joins and partial aggregations. While SPARQL analytical queries with unbound properties were not considered in this work, proposed optimizations in this paper can be extended based on NTGA-based optimizations in [32] to support composite graph patterns involving unbound-property triple patterns.

6. CONCLUSION AND FUTURE WORK

In this paper, we presented an algebraic optimization of SPARQL analytical queries that enables shared execution of common subexpressions across related groupings. Such a refactoring allows parallel evaluation of independent aggregations with savings in I/O and processing costs, a critical requirement while supporting large scale RDF analytics on Cloud platforms. Experiments on real-world and synthetic benchmark datasets showed promising results for SPARQL queries with multi-aggregation constraints. A natural extension of this work is to support more complex OLAP queries on RDF data models.

APPENDIX

A. SPARQL ANALYTICAL QUERIES

In this section, we provide a subset of evaluated SPARQL analytical queries with multiple grouping-aggregation constraints. The complete set of evaluated queries and Hive scripts are available on the project website [2].

G5. Retrieve drug-like compounds in PubChem that share common targets with Dexamethasone in the DrugBank (count targets per compound).

```
SELECT ?cid (COUNT(?cid) as ?active_assays) {
  ?b CID ?cid; outcome ?a; Score ?s1; gi ?gi .
  ?u gi ?gi; geneSymbol ?g .
  ?di gene ?g; DBID ?dr .
  ?dr Generic_Name "Dexamethasone" .
} GROUP BY ?cid
```

G6. Retrieve compounds in PubChem that are active towards targets in a given pathway (MAPK signalling pathway) in KEGG pathway dataset.

```
SELECT ?cid (COUNT(?cid) as ?active_assays) {
  ?b CID ?cid; outcome ?a; Score ?s1; gi ?gi .
  ?u gi ?gi .
  ?pathway protein ?u; Pathway_name ?pname .
  FILTER regex(?pname, "MAPK signaling pathway", "i")
} GROUP BY ?cid
```

G7. Retrieve pathways in the KEGG dataset that contain targets with drugs associated with hepatotoxicity (analyse side-effect hepatomegaly).

```
SELECT ?pid (COUNT(?pid) as ?count) {
  ?sider side_effect ?se; cid ?cid .
  FILTER regex(?se, "hepatomegaly", "i")
  ?dr CID ?cid .
  ?target DBID ?dr; SwissProt_ID ?u .
  ?pathway kegg:protein ?u; pathwayid ?pid .
} GROUP BY ?pid
```

MG1. Compare the average price of products per feature vs. price across all features (ProductType1).

```
SELECT ?f ?sumF ?cntF ?sumT ?cntT {
  { SELECT ?f (COUNT(?pr2) ?cntF) (SUM(?pr2) ?sumF)
    {?p2 type ProductType1; label ?l2; productFeature ?f.
     ?off2 product ?p2; price ?pr2 .
    } GROUP BY ?f
  }
  { SELECT (COUNT(?pr) As ?cntT) (SUM(?pr) As ?sumT)
    {?p1 type ProductType1; label ?l1 .
     ?off1 product ?p1; price ?pr .
    } } }
```

MG3. Compare the average price of products per country-feature vs. price per country across all features (for products of type ProductType1).

```
SELECT ?f ?c ?sumF ?cntF ?sumT ?cntT {
  { SELECT ?f ?c (COUNT(?pr2) ?cntF) (SUM(?pr2) ?sumF)
    {?p2 type ProductType1; label ?l2; productFeature ?f.
     ?off2 product ?p2; price ?pr2; vendor ?v2 .
     ?v2 country ?c .
    } GROUP BY ?f ?c
  }
  { SELECT ?c (COUNT(?pr) As ?cntT) (SUM(?pr) As ?sumT)
    {?p1 type ProductType1; label ?l1 .
     ?off1 product ?p1; price ?pr; vendor ?v1 .
     ?v1 country ?c .
    } GROUP BY ?c
  } }
```

MG6. Compare the count of targets for a chemical compound and gene combination vs. targets per compound (across all genes).

```
SELECT ?cid ?g1 ?aPerCG ?aPerC {
  { SELECT ?cid ?g1 (COUNT(?cid) as ?aPerCD)
    {?b1 CID ?cid; outcome ?a1; Score ?s1; gi ?gil .
     ?u1 gi ?gil; geneSymbol ?g1 .
     ?di1 gene ?g1; DBID ?dr1 .
    } GROUP BY ?cid ?g1
  }
  { SELECT ?cid (COUNT(?cid) as ?aPerG)
    {?b CID ?cid; outcome ?a; Score ?s; gi ?gi .
     ?u gi ?gi; geneSymbol ?g .
     ?di gene ?g; DBID ?dr .
    } GROUP BY ?cid
  } }
```

MG9. Compare no. of medline publications per gene vs. total count.

```
SELECT ?gs ?pPerGene ?pT {
  { SELECT ?gs (COUNT(?gs) as ?pPerGene)
    {?g geneSymbol ?gs .
     ?pmid gene ?g; side_effect ?se .
    } GROUP BY ?gs
  }
  { SELECT (COUNT(?gs1) as ?pT)
    {?g1 geneSymbol ?gs1 .
     ?pmid1 gene ?g1; side_effect ?se1 .
    } } }
```

MG11. Compare the count of journals funded by grant agencies of a country with the total count of journals published.

```
SELECT ?c ?cntC ?cntT {
  { SELECT ? (COUNT(?g) as ?cntC)
    {?pub journal ?j; grant ?g .
     ?g grant_agency ?ga; grant_country ?c .
    } GROUP BY ?c
  }
  { SELECT (COUNT(?g1) as ?cntT)
    {?pub1 journal ?j1; grant ?g1 .
     ?g1 grant_agency ?ga1 .
    } } }
```

MG13. Compare the number of medical subject headings (MeSH) associated per author and publication type with total MeSH per publication type.

```
SELECT ?a ?pty ?perPT ?perAPT {
  { SELECT ?a ?pty (count(?m) as ?perAPT)
    {?pub pub_type ?pty; mesh_heading ?m; author ?a .
     ?a last_name ?ln .
    } GROUP BY ?a ?pty
  }
  { SELECT ?pty (count(?m1) as ?perPT)
    {?p1 pub_type ?pty; mesh_heading ?m1; author ?a1 .
     ?a1 last_name ?ln1 .
    } GROUP BY ?pty
  } }
```

MG16. Compare the number of compounds associated with publications of type "News" (higher selectivity than Journal Articles).

```
SELECT ?ln ?perA ?allA {
  { SELECT ?ln (count(?chem) as ?perA)
    {?pub pub_type "News"; chemical ?ch; author ?a .
     ?a last_name ?ln .
    } GROUP BY ?ln
  }
  { SELECT (count(?chem1) as ?allA)
    {?pub1 pub_type "News"; chemical ?ch1; author ?a1 .
     ?a1 last_name ?ln1 .
    } } }
```

MG18. Count journal articles per author and grant-awarding country and compare with total journal articles per county (across authors).

```
SELECT ?c ?a ?perC ?perAC {
  { SELECT ?c ?a (count(?g) as ?perAC)
    {?p pub_type "Journal Article"; author ?a; grant ?g.
     ?g grant_agency ?ga; grant_country ?c .
    } GROUP BY ?c ?a
  }
  { SELECT ?c (count(?g1) as ?perC)
    {?pub1 pub_type "Journal Article"; grant ?g1 .
     ?g1 grant_agency ?ga1; grant_country ?c .
    } GROUP BY ?c
  } }
```

RDF-TX: A Fast, User-Friendly System for Querying the History of RDF Knowledge Bases

Shi Gao Jiaqi Gu Carlo Zaniolo
University of California, Los Angeles
{gaoshi, gujiaqi, zaniolo}@cs.ucla.edu

ABSTRACT

Knowledge bases that summarize web information in RDF triples deliver many benefits, including providing access to encyclopedic knowledge via SPARQL queries and end-user interfaces. As the real world evolves, the knowledge base is updated and the evolution history of entities and their properties becomes of great interest to users. Thus, users need query tools of comparable power and usability to explore such evolution histories or flash-back to the past. An integrated system that supports user-friendly queries and efficient query evaluation on the history of knowledge bases is required. In this paper, we introduce (i) SPARQL^T, a temporal extension of SPARQL that expresses powerful structured queries on temporal RDF graphs, (ii) an efficient in-memory query engine that takes advantage of compressed multiversion B+ trees to achieve fast evaluation of SPARQL^T queries, and (iii) a query optimizer that improves selectivity estimation of temporal queries and generates efficient join orders using the statistics of temporal RDF graphs. The performance and scalability of our system are validated by extensive experiments on real world datasets, which shows significant performance improvement comparing with other approaches.

1. INTRODUCTION

Knowledge bases that summarize valuable information in the RDF format are rapidly growing in terms of scale and significance and playing a crucial role in many applications such as semantic search and question answering. The extraordinary success of crowdsourcing and text mining for knowledge discovery makes it easy to generate and update the information in the knowledge bases. In fact, large knowledge bases undergo frequent changes. Table 1 lists the statistics of Wikipedia Infobox edit history, which shows that updates are quite common in many properties: e.g., on average each value in the population property of the city pages is updated more than 7 times. This is not specific to Wikipedia, but also happens in other knowledge repositories.

The management of historical information has emerged as a critical issue for knowledge bases. In fact, timestamping is an important part of the provenance information that is associated with each RDF triple in the knowledge base. The evolution history of knowl-

Category	Property	Average Number of Updates
Software	Release	7.27
Player	Club	5.85
Country	GDP(PPP)	11.78
City	Population	7.16

Table 1: Statistics of Wikipedia Infobox Edit History

edge bases captures and describes the change of real world entities and properties, and thus is of great interest to users. However, the size of the history is very large and the schema of knowledge base is also under evolution, which presents challenges in query language, query processing and indexing.

As the RDF model for representing knowledge bases is gaining great popularity, the importance of managing and querying the evolution history of knowledge bases is also recognized. Gutierrez et al. [17] extended the RDF model with time elements and several approaches [16, 29, 30, 32] have been proposed to support the queries on temporal RDF datasets. Most previous works employ relational databases and RDF engines to store temporal RDF triples and rewrite temporal queries into SQL/SPARQL for evaluation. The languages proposed in these works use an interval-based temporal model which leads to complex expressions for temporal queries, e.g., those requiring joins and coalescing [12, 33]. At the physical level, previous approaches exploit indexes such as tGrin [30] to accelerate the processing of simple temporal queries, but they do not explore the use of general temporal indices and query optimization techniques. This limits their scalability and performance on large knowledge bases and for complex queries.

In this paper, we describe a vertically integrated system RDF-TX (RDF Temporal eXpress) that efficiently supports the data management and query evaluation of large temporal RDF datasets while simplifying the temporal queries for SPARQL programmers and consequently, for end-user interfaces facilitating the expression of the same queries. To support the queries over the evolution history of knowledge bases, we propose efficient storage and index schemes for temporal RDF triples using multiversion B+ tree [7] and implement a query engine which achieves fast query evaluation by taking advantage of comprehensive indices. We also build a query optimizer that generates efficient join orders using a cost-based model and the statistics of temporal RDF graphs.

We propose a general and scalable solution for the problem of managing and querying massive temporal RDF data based on three main contributions:

- We propose SPARQL^T, a temporal extension of the structured query language SPARQL based on a point-based temporal model which simplifies the expression of temporal joins and eliminates the need for temporal coalescing. This approach makes possible end-user interfaces, such as those in [6,

15], where queries are entered via simple by-example conditions in the infoboxes of Wikipedia pages.

- We present an efficient main memory system RDF-TX for managing temporal RDF data and evaluating SPARQL^T queries. Our system uses multiversion B+ tree (MVBT) to store and index temporal RDF triples. An effective delta encoding scheme is introduced to reduce the storage overhead of indices. The algorithms on MVBT are extended and optimized to exploit the characteristics of the compression scheme and query patterns. Experimental evaluation demonstrates superior performance and scalability of RDF-TX compared with other approaches.
- We implement a query optimizer that generates the efficient join orders of SPARQL^T query patterns using the statistics of temporal RDF graphs. To manage temporal statistics, we introduce compressed Multi-Version SB Trees (MVSBT) that provide highly accurate estimation of statistics with a small storage overhead.

The rest of this paper is organized as follows. Section 2 provides an overview of RDF-TX system and temporal RDF model. Then we present the SPARQL^T query language in Section 3. Section 4 describes our storage model and index compression techniques. The query evaluation techniques are discussed in Section 5. Section 6 introduces a query optimizer for join order optimization. We evaluate our system on real world datasets in Section 7, and discuss related work in Section 8. Finally, we conclude in Section 9.

2. OVERVIEW AND DATA MODEL

In this section, we discuss the challenges of supporting temporal queries against the history of knowledge bases and provide a general overview of the RDF-TX system. Then we review the temporal RDF model introduced in [17].

2.1 Overview

The addition of temporal information to the basic RDF model poses difficult challenges that parallel those encountered by researchers working on extending the relational model with temporal information. A first lesson learned from that experience is that supporting temporal event information is simple, but state-based temporal information presents many challenges. In fact, timestamps can be associated with temporal events via standard RDF predicates (e.g. *birthDate* and *establishedYear*). Then they can be queried as any ordered domain.

Supporting state information is much more complex, as demonstrated by the many temporal representations and constructs proposed [12, 13, 25, 33] and the rich set of interval-based operators required [5]. For instance, answering a simple query such as “Who was the president of University of California on 9/9/2009?” requires determining the time interval that contains 9/9/2009. In a valid time temporal database, the curators are responsible for supplying these timestamps, thus creating a valid-time history. However, in DBpedia and other web repositories, the curators do not update timestamps directly: instead they update web pages and associated Infoboxes to reflect the changes that occurred in the domain they describe. Thus, readers of the web page will notice a change of the president name from *Mark Youdof* to *Janet Napolitano*. The date and time of this change, i.e. the timestamp in which the update was executed by the system, is known as transaction time (or system time) and, as such, it is constructed from the system log.

Whereas tardy curators will eventually enter the correct valid time, any tardiness of their actions adds permanently to the imprecision of a transaction time databases. Nevertheless, when as in

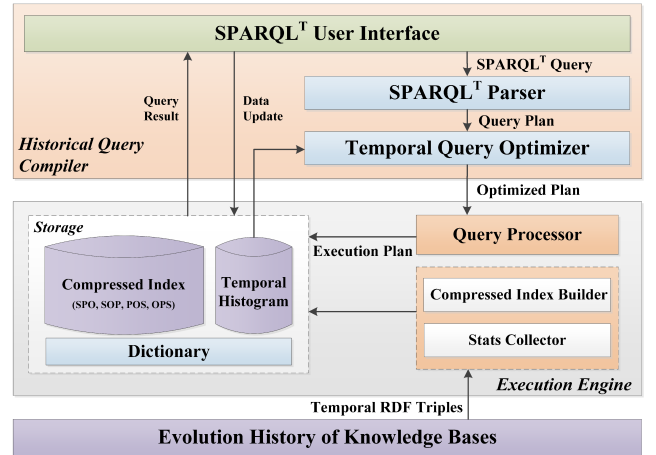

Figure 1: RDF-TX Architecture

the case of Wikipedia, valid time histories are not available, transaction time history will provide a reasonable substitute. Indeed, since the varying tardiness with which Wikipedia Infoboxes are refreshed has not damaged their popularity, it is reasonable to expect that databases describing their system time history will be equally popular, particularly when users are given tools to compensate for temporal imprecision¹.

Moreover, there are other scenarios in which transaction time histories are needed:

- *History Browsing and Analyzing* [14, 15]. The history of knowledge base captures the revisions of knowledge, which is of great interest for editors and users to understand how the knowledge is evolved and updated.
- *Knowledge Auditing and Verification* [35]. Timestamping, as an important part of provenance, is important for ensuring the quality of facts in many applications. A system with temporal query support also provides administrators with previous states of knowledge bases for auditing purposes.
- *Backup and Recovery*. The history of knowledge bases can be used to backup and recover missing information.

In this paper we present query extensions and an efficient system for managing and querying the transaction time history of knowledge bases. However, the user model and query constructs apply to valid-time histories as well. At the physical level, although the storage structure is designed for the transaction time model, our implementation remains effective for most valid-time histories as discussed in our technical report [2].

Figure 1 shows the high level architecture of our system, which can be divided into two main components as follows.

Historical Query Compiler. To express queries against the history of knowledge bases, we introduce a temporal extension of SPARQL called SPARQL^T. Users can write and submit SPARQL^T queries through our interface. Then the SPARQL^T queries are compiled to query plans represented as graphs of query patterns and passed to the temporal query optimizer. The optimized query plans are submitted to the *Execution Engine* for evaluation.

Execution Engine. In our engine, the historical information is represented as temporal RDF triples and stored using compressed MVBT indices that support fast query processing. The query processor transforms the query plans from compiler to execution plans expressed in query operators (e.g. temporal selection and join) and executes them on the compressed MVBT indices.

¹Provenance annotations that record the tardiness of refreshes can go a long way to cure this problem.

Predicate	Object	Timestamp
president	Mark Yudof	06/16/2008 ... 09/29/2013

Table 2: Temporal RDF Triples for *University of California*

2.2 Data Model

Knowledge bases such as DBpedia [10] and Yago2 [18] can be represented as RDF graphs which consist of RDF triples in the format (*subject*, *predicate*, *object*). The subject and predicate of an RDF triple are elements from the set of Uniform Resource Identifiers \mathcal{U} , while the object is a URI from \mathcal{U} or a value from the set of literals \mathcal{L} . For example, the RDF triple for “The president of University of California is Mark Yudof.” is:

- *subject*: http://www.w3.org/edu/University_of_California
- *predicate*: <http://www.w3.org/elements/president>
- *object*: http://www.w3.org/people/Mark_Yudof

For the sake of simplicity, we do not discuss the concept of blank nodes and assume the prefix parts of URI (e.g. <http://www.w3.org/edu/>) are given. Above RDF triple is represented as (*University of California*, *president*, *Mark Yudof*).

Since the basic RDF model is designed for static information, we represent the evolution history of knowledge bases using the temporal RDF model proposed in [17] that extends the RDF model with temporal elements. Each RDF triple is annotated with a temporal element to represent the time when this triple is valid. Formally, given a point-based temporal domain \mathcal{T} , a *Temporal RDF Graph* consists of a set of temporal RDF triples where each temporal RDF triple is a RDF triple (s, p, o) annotated with a temporal element $t \in \mathcal{T}$. A set of temporal RDF triples with consecutive time points $\{(s, p, o) [t] \mid t_s \leq t \leq t_e\}$ are encoded using the interval-based expression as: $(s, p, o) [t_s \dots t_e]$.

The evolution history of subject *University of California* is represented as a set of temporal RDF triples, as shown in Table 2. All the triples share the same subject *University of California*. We use DAY as the granularity of time and *now* as the current time. Typically, one triple is valid over several days, which we represent with ... between the start day and the end day (start and end included): e.g. [07/01/2013 ... 06/30/2014] represents all the days between 07/01/2013 and 06/30/2014.

3. SPARQL^T QUERY LANGUAGE

To support temporal queries over the history of knowledge bases, we propose a temporal extension of SPARQL called SPARQL^T. One main difference between SPARQL^T and previous works is the choice of the temporal model. Many existing works [29, 30, 32] use the interval-based model because of efficiency considerations. However, to express temporal queries, the interval-based representation requires additional operators such as temporal interval overlap, intersect and coalesce, which introduce complications and difficulties [12, 42], particularly for casual users working with friendly wysiwyg interfaces. Therefore, we use a point-based temporal model that resolves these problems at the logical level; however at the physical level we retain the interval representation for efficiency

reasons. Queries on the point-based model can be easily mapped into equivalent ones on the interval-based model for execution.

3.1 SPARQL^T Syntax

SPARQL^T extends SPARQL with temporal patterns and constructs to query temporal RDF data. To simplify our presentation, we first review the standard syntax of SPARQL [28] and then explain our temporal extension.

SPARQL graph patterns are defined as follows:

- A SPARQL graph pattern is a triple $\{s \ p \ o\}$ from $(\mathcal{U} \cup \mathcal{L} \cup \mathcal{V}) \times (\mathcal{U} \cup \mathcal{V}) \times (\mathcal{U} \cup \mathcal{L} \cup \mathcal{V})$ where \mathcal{V} is a set of variables.
- If S and S' are SPARQL graph patterns and F is a filter clause, $(S \text{ AND } S')$, $(S \text{ OPT } S')$, $(S \text{ UNION } S')$ and $(S \text{ FILTER } F)$ are also graph patterns.

where $(S \text{ AND } S')$, $(S \text{ OPT } S')$ and $(S \text{ UNION } S')$ denote the conjunction, optional and union graph patterns.

Temporal queries against the history of knowledge bases are expressed as SPARQL^T graph patterns.

SPARQL^T graph patterns are defined as follows:

- A SPARQL^T graph pattern is a tuple $\{s \ p \ o \ t\}$ from $(\mathcal{U} \cup \mathcal{L} \cup \mathcal{V}) \times (\mathcal{U} \cup \mathcal{L}) \times (\mathcal{U} \cup \mathcal{L} \cup \mathcal{V}) \times (\mathcal{T} \cup \mathcal{V})$.
- If P and P' are two SPARQL^T graph patterns and F' is a filter clause, $(P \text{ AND } P')$ and $(P \text{ FILTER } F')$ are also SPARQL^T graph patterns.

Where F' is constructed using the elements from $\mathcal{U} \cup \mathcal{L} \cup \mathcal{T} \cup \mathcal{V}$, comparison symbols, logical connectors and the temporal built-in functions discussed next. In SPARQL, there are 8 types of graph patterns as: S, P, O, SP, SO, PO, SPO, and full scan. For example, SP refers to a query pattern in which subject and predicate are constants and object is a variable. SPARQL^T supports 16 types of graph patterns, which enable the expression of many interesting queries over temporal RDF graphs.

$(P \text{ UNION } P')$ and $(P \text{ OPT } P')$ are not supported in current SPARQL^T, and their implementation is planned for the future. In current state, SPARQL^T supports efficiently all the queries described in this paper, including the applications discussed in Section 2.1. In passing we observe that they follow the patterns of (i) retrieving information from a previous version of knowledge bases, and (ii) joining the information with similar keys and timestamps. These two scenarios correspond to two operators: single graph pattern matching and temporal join that are supported very efficiently in our system.

Time Representation and Functions. In SPARQL^T, timestamp is from a discrete time domain with a minimum unit as chronon [13]. We define two temporal types: *dateTime* and *period*. *dateTime* corresponds to a single timestamp. *period* corresponds to a set of consecutive timestamps, represented as a pair of two datetime points. For timestamps, SPARQL^T is equipped with YEAR/MONTH/DAY functions to enable flexible temporal conditions. For periods, we define two built-in functions *TSTART* and *TEND* to return the first and last element in a set of consecutive timestamps.

Many temporal queries involve the reasoning of duration. Thus we define a built-in function *LENGTH* that counts the number of time units (we use DAY as the minimum unit in this paper) within the same consecutive period of time. If one fact is associated with multiple intervals, we return the length of max duration. Another similar function *TOTAL_LENGTH* is defined to compute the total length of all intervals.

3.2 Semantics and Examples

SPARQL^T is a graph matching language for querying temporal RDF data. The input of a SPARQL^T query is a temporal RDF

graph and the output is a set of mappings that replace the variables with values from the input temporal RDF graph. The operators of SPARQL are extended to manipulate the temporal element t of SPARQL^T graph patterns. For single pattern matching, the query result is the set of temporal RDF triples that match the graph pattern and the filter clause. If there are two or more patterns in the query, the results of single pattern matching are joined. Due to space limitations, we omit the discussion of formal semantics which can be instead found in our technical report [2]. All the syntax discussed in previous section are implemented in RDF-TX. Next we illustrate the usage of SPARQL^T via several examples.

Temporal Selection. We first discuss *temporal selection* queries that have one query pattern (a four-element tuple $\{s, p, o, t\}$). An example of temporal selection query is the “when” query that retrieves the valid timestamps of given facts. Users only need to specify the values for (s, p, o) and a variable for the temporal element.

EXAMPLE 1. When did Janet Napolitano serve as the president of University of California.

```
SELECT ?t
{University_of_California president Janet_Napolitano ?t}
```

In the query result, the timestamps will be displayed in the compact format $[t_s \dots t_e]$. Running Example 1 against the temporal RDF graph in Table 2 returns $[09/30/2013 \dots now]$. Another common type of temporal selection queries retrieves information from a previous version of the knowledge base. The temporal constraints (e.g. within a period) can be specified in the FILTER clause.

EXAMPLE 2. Find the budget of University of California in 2013.

```
SELECT ?budget
{University_of_California budget ?budget ?t.
FILTER(YEAR(?t) = 2013)}
```

EXAMPLE 3. Find each person who served as the president of University of California for more than one year before 2010.

```
SELECT ?person ?t
{University_of_California president ?person ?t.
FILTER(YEAR(?t) <= 2010 && LENGTH(?t) > 365 DAY)}
```

Temporal Join. More complex queries often use temporal joins which, in SPARQL^T, are expressed by multiple query patterns that share the same temporal element. General temporal join may involve both key and temporal dimensions.

EXAMPLE 4. Find the name of the university in which Mark Yudof served as the president and the number of undergraduate students when he was in office.

```
SELECT ?university ?number ?t
{?university undergraduate ?number ?t.
?university president Mark_Yudof ?t.}
```

Queries using multiple temporal joins are rather simple to express in SPARQL^T, whereas in languages based on an interval-based temporal model, such queries tend to be much more complex. For example, if users want to search the number of undergraduate and graduate students when Mark Yudof was in office, we only need to add one more query pattern: $\{?university graduate ?number2 ?t\}$ to Example 4. If we switch to interval-based model, the query will consist of three query patterns and three temporal conditions: $?I_1 overlap ?I_2, ?I_1 overlap ?I_3, ?I_2 overlap ?I_3$ where $?I_1, ?I_2, ?I_3$ are three variables for intervals.

Besides temporal join, the point-based query patterns also support the expression of other temporal operations such as MEET and CONTAIN using the built-in functions TSTART and TEND.

EXAMPLE 5. Find who succeeded Mark Yudof as the president of University of California.

```
SELECT ?successor
```

```
{University_of_California president Mark_Yudof ?t1.
University_of_California president ?successor ?t2.
FILTER(TEND(?t1) = TSTART(?t2)).}
```

4. STORAGE AND INDEXING

Since the performance of query engines is heavily influenced by its use of indices, it is important to choose an appropriate index structure as well as storage schema for the temporal RDF data.

A natural approach followed by previous works [29] consists in managing temporal RDF triples using existing RDBMS. However, for searching both RDF information and temporal information, two sets of indices are required, and this results in significant costs in storage and retrieval time, which are shown in Section 7. A second natural approach will be using RDF engines, such as Jena and Virtuoso, which have seen recent improvements in performance and functionality. However, this requires the standard RDF reification approach in which a temporal RDF triple is represented as an entity instance with five properties: subject, predicate, object, start time and end time. Thus we need to use five triples for each temporal fact, whereby the space cost increases along with complexity of the queries and time required to optimize and execute them.

Therefore, rather than modifying and extending existing systems we design and build a new system that integrates advanced indexing and data compression techniques into an architecture conceived for efficient support of SPARQL^T queries

4.1 Index Scheme

Many index structures [7, 19, 22, 24] have been proposed for temporal data. Each index has its own strength and they have shared issues such as space overhead and limited support for general temporal queries.² In this project, we employ Multiversion B+ Tree (MVBT) to index temporal RDF data for the following reasons. First, MVBT is a bi-dimensional index with asymptotic worst-case guarantee and delivers good performance in real world datasets. Second, we propose an effective approach to compress MVBT which greatly reduces the space cost. The algorithms [8, 41] are extended and optimized on compressed MVBT to enable fast index scan and join. Next we briefly review the structure of MVBT and discuss the index scheme in RDF-TX system.

4.1.1 MVBT

Multiversion B+ Tree [7] is a temporal index structure with optimal worst case guarantees for data insert, update, and delete. The complexity of a temporal query in version i is asymptotically equal to the complexity of the query on a B+ tree that maintains all the data valid in version i . Rather than a single tree, an MVBT is actually a forest of trees. It has multiple root nodes and each of them corresponds to a temporal partition of data, as shown in Figure 2(a). An entry in the MVBT node can be represented as $(key, start version, end version, data value/pointer)$ where key is unique for a given version and $start version$ and $end version$ together denote the live period of data. An entry that stores data inserted in version i carries a period of (i, now) . We denote an entry with end version now as a live entry. The delete operation modifies the end version of a live entry.

A simple example of MVBT insertion/deletion is shown in Figure 2(b). We first insert five values into an empty MVBT in Version 1, which results in an MVBT tree (i). Then we insert key 14 in Version 2 and delete key 46 in Version 3. The MVBT index becomes

²A detailed discussion of temporal index can be found in Section 8.

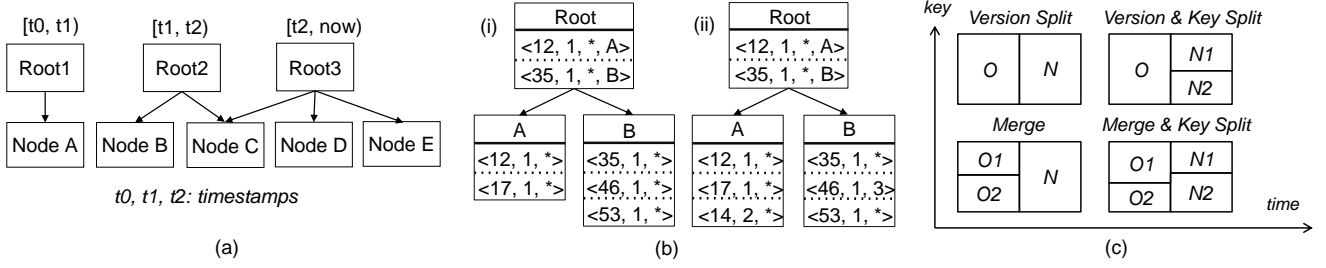

Figure 2: MVBT Example (a) Index Structure; (b) Data Insertion and Deletion; (c) Node Structure Changes.

(ii) with $\langle 14, 2, * \rangle$ added to Node A and $\langle 46, 1, * \rangle$ changed to $\langle 46, 1, 3 \rangle$ in Node B.

To guarantee the performance, MVBT has *weak version condition* that there must be at least k live entries in a live node. When there are too many entries or not enough live entries (*weak version underflow*) in an MVBT node, node structure changes (version split or merge) are triggered. After structure changes, the number of live entries in a node should be in the range $[k_l, k_h]$ (*strong version condition*), which prevents long sequences of split and merge operations.

There are four types of node structure changes in MVBT, illustrated in Figure 2(c). We assume that an insertion results in too many entries in a node O . Then a *Version Split* is performed that copies all the live entries in O to a new node N . If node N has more than k_h entries, then an additional key split is performed that splits N into two nodes, as shown in *Version & Key Split*. If N has less than k_l entries, *Merge* is triggered.

Assume we need to perform *Merge* operation on the node $O1$. MVBT identifies a live sibling node $O2$, performs version split and copies the live entries into the new node N . If node N has more than k_h live entries, a key split is performed immediately, as shown in *Merge & Key Split*. Due to the space limitation, we address the readers to [7] for more details of MVBT node structure changes.

4.1.2 Indexing Temporal RDF

In RDF-TX all the data and indices are stored in the main memory. We implement in-memory MVBT to index the temporal RDF triples. The insertion of an interval-encoded RDF triple $\{(s, p, o) [t_s, t_e]\}$ on MVBT index M is decomposed into two operations: (i) insert data item (s, p, o) into M at time t_s ; (ii) delete data item (s, p, o) at time t_e .

Since the variable may be located in any position of (s, p, o) , we create four MVBT indices (SPO, SOP, POS, OPS) for different orders of keys (s, p, o) . These MVBT indices cover all 16 SPARQL^T graph patterns. For example, the MVBT index for temporal RDF triples in POS order can cover four patterns: P, PT, PO, POT. In query evaluation, the query engine parses the SPARQL^T prefix patterns to identify the corresponding MVBT index.

We employ dictionary encoding in the index construction, which reduces the index size and avoids the slow comparison between long string literals. Thus RDF-TX replaces the literals with dictionary IDs, and the triples that consist of IDs and timestamps are inserted into our indices. The mapping relations are maintained in our in-memory dictionary for index update and query evaluation. Since the main space cost in our indices is the large number of MVBT entries, dictionary encoding only reduces space cost by 10% - 20%. After dictionary encoding, we exploit delta compression which significantly reduces the space cost of MVBT indices.

4.2 Index Compression

For the Wikipedia Infobox History, the size of one standard MVBT index implemented in Java is 1.5–2.2 times of the raw data. More-

over, a temporal RDF graph requires four MVBT indices. If a naive approach is used, comprehensive indexing of temporal RDF data becomes prohibitively expensive. Thus effective compression techniques are needed for large scale datasets.

We observe two characteristics of MVBT. First, the entries in the MVBT node are sorted and neighboring entries often share the same prefix, which could be utilized to reduce space cost. Second, all the node structure operations start from *version split*. This guarantees the query performance but leads to a lot of long intervals. Given these characteristics, we introduce an effective delta encoding method to compress MVBT indices.

4.2.1 Compression Techniques

We design a compression scheme for variable delta encoding of MVBT entry. An MVBT entry for temporal RDF data consists of five values: $(v_1, v_2, v_3, t_s, t_e)$ where v_1, v_2, v_3 are elements in RDF triples. We store the minimum values for keys and timestamps in each node as base values. Since the data entries are sorted by start version (t_s) and key, most entries have very close start versions. Therefore for t_s , we only keep the minimal value of each node, and compute and store the delta start versions. For t_e , the compression rules are as follows: (i) if the valid interval (t_s, t_e) is a short interval, t_e is stored as the length of intervals; (ii) if the valid interval is long, t_e is stored as the delta value between t_e and minimum t_e in the node; (iii) if the valid interval is a live interval (t_e is *now*), a special flag is set and t_e is stored as empty. Other values (v_1, v_2, v_3) are compressed as the delta values (i) between current value and the value in neighbor entry or (ii) between current value and minimum value in leaf node.

The compressed values are stored in a compact byte array. Figure 3(a) illustrates the format of compressed MVBT entry. Every entry consists of three parts: header, key block (v_1, v_2 , and v_3), and time block (t_s and t_e). A normal header (2 bytes) contains a flag (H Flag, 1 bit) for header type (normal/compact), a payload (13 bits in total, 7 bits for key block and 6 bits for time block) that stores the number of bytes for each delta value, and the t_e flag (2 bits) that records the compression rule for t_e . For the delta values in key block, we use 1 bit to record how the delta is computed (with neighbor or with node minimum value).

We observe that in large datasets, it is very common that two neighboring MVBT entries (i) share at least one element in key block; (ii) have very close t_s (delta size ≤ 4 bytes) (iii) both t_e are *now*. Thus for these entries, we propose a compact header which consists of 1 bit header type and 7 bits payload (for two delta values in key block and t_s delta value).

There is a trade-off between the compression ratio and query performance. Since the number of index nodes is much smaller than the number of leaf nodes and the index nodes are accessed more frequently than leaf nodes, we only compress the leaf nodes of MVBT indices. As shown in evaluation (Section 7), the size of compressed MVBT is about 24% of standard MVBT.

We build MVBT indices for different subsets of Wikipedia dataset

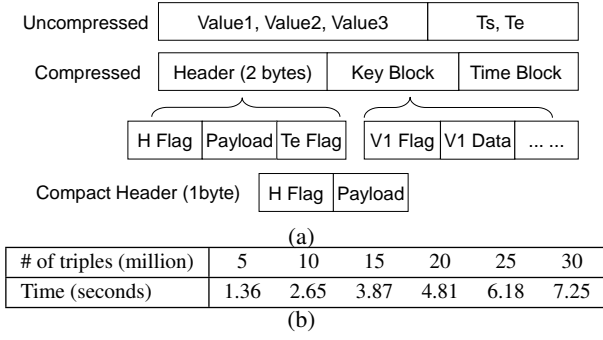

Figure 3: (a) Compressed MVBT Entry (b) Compression Time

and then test the time for compressing MVBT entries, as shown in Figure 3(b). The result shows that it takes very little time to apply the delta encoding technique. Given an MVBT index built from 30 million temporal RDF triples, the time for compressing all the leaf nodes is only 7.25 seconds.

4.2.2 Index Maintenance

An important principle of index compression is to reduce the storage overhead while maintaining the performance of index update and search. For data insertion, we first look up index nodes and identify the leaf node to be updated. In the leaf node, we decompress the start versions (t_s) to find the position of input start version i and compute the delta values of input data. Then we modify the $(i + 1)$ th entry if its delta values are changed. One issue is that we need to scan from the beginning of all entries. To address this issue, we add a checkpoint in each node that stores the position of MVBT entry with largest t_s . Then in data insertion, since the t_s of input data must be larger than existing t_s , we only decompress the entries after checkpoint. Deletion in MVBT only updates the end version of a live entry. Thus we simply scan all the entries and modify the t_e of the matched entry. As shown in Section 7, insertion/deletion on compressed MVBT only takes 5% more time than standard MVBT.

5. QUERY PROCESSING

In this section, we present the design and implementation of RDF-TX query engine, which makes use of MVBT to process the temporal operations of the language.

5.1 Compiling SPARQL^T Query

The overall evaluation of SPARQL^T queries consists of four steps:

- Parse the input query and translate point-based query patterns to interval-based query patterns.
- Construct a query plan. The plan is represented as a graph in which each node is an interval-based query pattern.
- When the query contains multiple temporal joins, optimize the query plan to improve the join order.
- Translate the query plan to an execution plan that is evaluated on compressed MVBT indices.

Next we elaborate each step with more details.

Translating Query Patterns. Since the temporal RDF graph is stored as interval-based temporal RDF triples, we translate the point-based SPARQL^T query patterns to the interval-based patterns that can be converted to range queries and executed on MVBT. For key elements, we take the literals as prefix and convert the unknown parts to key ranges. For temporal element (t), if there exist temporal constraints in the FILTER clause, we generate time ranges based

Figure 4: An Example of MVBT Backward Link

on the constraints; otherwise, the default range is $[0, now]$ where 0 refers to the minimum time point. Consider the query pattern $\{University\ of\ California\ budget\ ?budget\ ?t\} (YEAR(?t) = 2013)$ in Example 2. The interval-based query pattern can be described as a query region with key range and time range as follows:

- key range: $(University\ of\ California, budget, _) - (University\ of\ California, budget, \infty)$
- time range: $01/01/2013 - 12/31/2013$

Here $_$ and ∞ denote the extrema of the string domain.

Constructing and Optimizing Query Plan. The query engine generates a query plan that consists of interval-based query patterns from the first step. This query plan can be represented as a graph in which the edges between the nodes are added when two query patterns share the same variable. If there are multiple join operations, the query optimizer (discussed in Section 6) is called to find efficient query plans using the statistics of temporal RDF graphs.

Executing the query plan on MVBT. Lastly, the optimized plan is translated to an execution plan which is similar to the query plan in relational databases. Every query pattern is converted to an index scan operator on MVBT indices. Then the join operators are added based on the optimized join order. Finally, appropriate filter operators are added using the FILTER clause of SPARQL.

5.2 Executing Query Plan

Next we describe the implementation of index scan and temporal join in RDF-TX. Other operators (e.g. filter) are implemented similar to their counterparts of existing engines thus omitted.

5.2.1 Index Scan

We perform an index scan for each interval-based query pattern. For the index scan on MVBT, we employ the link-based range-interval algorithm [8] which introduces *Backward Link* in MVBT to process the range queries. The MVBT leaf nodes are equipped with backward links that point to the temporal predecessors. The index scan is performed as: (i) search all the nodes that intersect the right border of query region; (ii) follow the backward links of the nodes to find all the nodes that intersect query region; (iii) scan the leaf nodes found in the first two steps to retrieve the entries. An example of linked index scan is shown in Figure 4. The shadowed rectangle represents a query. MVBT nodes D and E are first visited. Then as the predecessor of D and E , node B is checked. Lastly, node A is visited.

5.2.2 Temporal Join

Temporal join represents one of the most expensive operations in the temporal query language, especially when the size of knowledge base is very large. Therefore we explore three types of joins: *Merge Join*, *Hash Join*, and *Synchronized Join*.

Merge join is very popular and widely used in existing SPARQL engines [27, 38]. These systems build indices for all permutations so that the optimizer leverages the indices to perform order-preserving merge joins. However, this does not work for MVBT index since the entries are sorted by time. We mainly use *Hash Join* in our query engine.

When the size of result is large, the cost of building a hash table may be very expensive. Thus we extend the synchronized join [41]. The basic idea of synchronized join is as follows: (i) synchronously find the set of all MVBT node pairs (e_1, e_2) that intersect each other and the right border of query region; (ii) join e_1 and e_2 ; (iii) join the predecessors of e_1 and e_2 by following the backward links. This algorithm avoids materializing the intermediate result, but it is much slower than hash-based join since one page and its predecessors are visited many times. So we optimize this algorithm by caching recently visited records; that is, given a page e from step (i), we cache the records in e and its predecessors, and perform joins between e and other pages. This optimized synchronized join is used when the query pattern in the join accesses a large portion of index (e.g. find all the triples valid in a certain period).

6. OPTIMIZATION

In RDF-TX, improper join orders may generate large intermediate results and slow down execution. Therefore, a natural step is to optimize complex SPARQL^T queries by finding efficient join orders. The key of join optimization is to efficiently estimate the costs of different join orders, which is not a trivial task for temporal queries. In this section, we present a query optimizer that uses estimated statistics of temporal RDF graph to optimize the orders of temporal joins in SPARQL^T queries.

6.1 RDF-TX Query Optimizer

For queries that involve multiple temporal joins, we implement a query optimizer that uses the bottom-up dynamic programming strategy [23] to find the cost-optimal query plans. Our optimizer generates multiple query plans and finds the plan with lowest estimated cost. A large query plan is generated by joining two small optimal query plans. The cost is computed based on the cardinalities of query patterns and intermediate results.

The cardinality estimation is a well-studied problem in relational databases and SPARQL engines [26, 27, 31]. To estimate the cardinality of join result, an effective approach is characteristic set [26]. In a RDF graph R , the characteristic set $SC(s)$ of a subject s is the set of related predicates: $SC(s) = \{p | \exists o, (s, p, o) \in R\}$.

The idea of characteristic set is that semantically similar subjects (e.g. University of California and University of Michigan) usually have the same characteristic set. For every characteristic set, the number of distinct subjects that belong to the characteristic set, and the number of occurrences of the predicates in these subjects are recorded and used to estimate the cardinality. For example, given a characteristic set $\{president, undergraduate\}$, there are 100 distinct subjects belong to this characteristic set. The numbers of occurrences for *president* and *undergraduate* are 150 and 110 respectively. Consider a SPARQL query with two query patterns:

```
SELECT ?s ?o1 ?o2 .
{?s president ?o1 .
?s undergraduate ?o2 . }
```

Suppose that only this characteristic set contains both predicates in the query. Then the result cardinality is estimated as: $100 \times \frac{150}{100} \times \frac{110}{100} = 165$.

Characteristic sets provide highly accurate estimation of cardinality. But it can not be used to estimate the cardinality of SPARQL^T queries since the statistics of temporal RDF graph vary on different time points. Consider following SPARQL^T query:

```
SELECT ?s ?o1 ?o2 ?t
{?s president ?o1 ?t.
?s undergraduate ?o2 ?t. }
```

Figure 5: An Example of MVSBT Entry Split

`FILTER(?t ≤ 01/01/2013) . }`

To estimate the cardinality of this SPARQL^T query, we need to know the number of subjects that (i) belong to the set of temporal RDF triples valid in the period $[0, 01/01/2013]$ and (ii) share the characteristics set $\{president, undergraduate\}$. These statistics change with time and none of existing data structures can provide estimation of these statistics. Thus we introduce a temporal histogram to maintain the statistics of temporal RDF data in next Section. With temporal histogram, the characteristics sets can be easily integrated into our query optimizer.

6.2 Temporal Histogram

The problem of estimating the statistics of temporal RDF data is similar to the temporal aggregation that computes the aggregate value in a certain period. Thus we propose Compressed MVSBT that extends the temporal aggregate index Multiversion SB Tree to maintain the statistics of characteristic sets.

6.2.1 MVSBT

MVSBT [39, 40] is a temporal index that combines the features of MVBT and SB Tree [37] and supports the dominance-sum query. Given key k and time t , it returns the aggregation value of data records with keys less than k and timestamps smaller than t .

Similar to MVBT, MVSBT is a forest of trees with multiple root nodes and each of them points to an SB Tree for a temporal partition of data. Each entry in MVSBT corresponds to a rectangle in the key-time space. The structure of MVSBT entry is as follows:

- Leaf Entry: $\langle k_s, k_e, t_s, t_e, v \rangle$
- Index Entry: $\langle k_s, k_e, t_s, t_e, v, ptr \rangle$

A leaf entry has a key range (k_s, k_e) , an interval (t_s, t_e) , and a value v . The key range and the interval represent the rectangle covered by this entry in the key-time space. v maintains the aggregate value. The index entry has one additional pointer ptr that points to a child node. The rectangles of the entries are mutually disjoint and the union of all the rectangles is equal to the whole key-time space.

The node structure of MVSBT is similar to MVBT while the insertion algorithm is quite different. First we need to review two concepts introduced in [39]. Given a point (k, t) , and max key value max_key , an entry is referred as *partly covered entry* if its key range intersects the range $[k, max_key]$ but not contained in this range; an entry is referred as *fully covered entry* if its key range is contained by the range $[k, max_key]$. When a new point $p(k, t)$ is inserted into a node N , the fully covered entries are vertically split at t . If there exists a partly covered entry, then p is inserted into the child page. If node N is in the leaf level, the partly covered entry is split into three entries based on point p . The node structure operations of MVSBT are similar to the ones of MVBT (Section 4.1.1) thus omitted.

An example of MVSBT for aggregate COUNT is shown in Figure 5. Figure 5(a) shows the initial entry of an empty MVSBT. The aggregate value is 0 since no point is inserted. Then one point with key 30 and timestamp 2 is inserted. The initial entry is split into three entries as shown in Figure 5(b). The entry on the top right corner has aggregate value 1 and other entries has aggregate value

Algorithm: leafEntrySplit(n_f, r, q)

Input: CMVSBT leaf node n_f , entry r , new point $p(k, t)$

```

1:  $r.c = r.c + 1$ 
2: if  $p.k > r.k_m$  then
3:    $r.k_m = p.k$ 
4:  $r.t_m = p.t$ 
5: if  $r.c = c_m$  then
6:   if  $r.k_m \neq r.k_s$  and  $r.t_m \neq r.t_s$  then
7:     // Split  $r$  to three entries
8:      $v' = r.c/2 + r.v$ 
9:      $r_1 = \text{new entry}(r.k_s, r.k_m, r.t_m, r.t_e, k_s, t_m, v', 0)$ 
10:     $r_2 = \text{new entry}(r.k_m, r.k_e, r.t_m, r.t_e, k_m, t_m, r.c/2, 0)$ 
11:     $n_f.add(r_1); n_f.add(r_2)$ 
12:     $r.t_e = r.t_m$ 
13:   else
14:     // Split  $r$  to two entries, similar to step 7 - 11, omit

```

Algorithm: indexEntrySplit(n_i, r, p)

Input: CMVSBT index node n_i , entry r , new point $p(k, t)$

```

1:  $r.list.add(p)$ 
2: if  $\text{length}(r.list) == l_m$  then
3:    $r_1 = \text{new entry}(r.k_s, r.k_e, p.t, r.t_e, \text{new list}(), r.ptr, r.c)$ 
4:    $n_i.add(r_1)$ 
5:    $r.t_e = p.t$ 

```

Figure 6: Algorithms for Entry Split in CMVSBT

0 since all the points in top right entry are larger than split point (30, 2). Suppose we have two queries (10, 1) and (40, 5). The first query point falls in the left entry and returns 0. The second query points falls in the top right entry and thus gets the result 1.

6.2.2 Compressed MVSBT

Although MVSBT has good performance on temporal aggregation, it takes too much space for storage. Since query optimization does not require very accurate estimates, we can trade accuracy with efficiency. Compressed MVSBT (CMVSBT) is based on the idea that instead of accurately recording the points and splitting entries for every new point, a CMVSBT entry contains m ($m \geq 1$) points. Then we can estimate the aggregate value using the ratio of covered space to full space. Instead of storing the exact values of points, we store the statistic values such as total number of points and max value. The structure of CMVSBT entry is as follows:

- Leaf Entry: $\langle k_s, k_e, t_s, t_e, k_m, t_m, v, c \rangle$
- Index Entry: $\langle k_s, k_e, t_s, t_e, list, ptr, c \rangle$

where k_s, k_e, t_s, t_e are for the key range and associated time interval. k_m and t_m store the max key value and time value of the points located in the rectangle of this entry; $list$ is a list of points; ptr is the pointer to a CMVSBT node; v and c are fixed and current statistic values. fixed statistic value refers to the aggregate value, while current statistic value refers to the aggregate value computed over the points contained in the current entry. The final statistic value is estimated by combining both values (discussed in Section 6.3).

Since the index nodes are visited more frequently than leaf nodes, we store the exact values of points in a list in the index nodes, while in leaf nodes we only maintain three statistics (k_m, t_m, c). The algorithm for data insertion in CMVSBT is similar to the one for MVSBT. Instead of splitting the entry for every input point, CMVSBT entry is split when the number of points in an entry is larger than the threshold. The split point is (k_m, t_m) . The algorithm for entry splitting in CMVSBT for COUNT is shown in Figure 6. Let c_m and l_m denote the thresholds for the number of points in leaf nodes and index nodes. When a new point $p(k, t)$ is inserted into compressed MVSBT, we look up the index nodes to find a set

Figure 7: An Example of CMVSBT Entry Split

of nodes N whose rectangles cover this point. In a leaf node n_f , if p falls in the rectangle, c is increased by 1, and the max values (k_m, t_m) are updated if $p.k > k_m$ or $p.t > t_m$. Then if $c = c_m$, we split the entry based on the position (k_m, t_m) . After split, the statistical values (v) of new entries will be equal to (i) $c/2 + v$ if the new entry has the same k_s with old one; (ii) $c/2$ otherwise (based on the logical splitting in MVSBT [40]). We use $c/2$ since we assume the points are uniformly distributed in the entry. The c of new entries are initialized to be 0. In an index node $n_i \in N$, if r_i is the lowest entry that fully covers p , p is appended to the end of $list$. Like MVSBT, compressed MVSBT also assumes that the data items come in nondecreasing time order. Thus $list$ is automatically sorted by time. If $\text{length}(list) = l_m$, the entry is split on $p.t$ and c is copied to new entry. If $r.k_m = r.k$ or $r.t_m \neq r.t_s$, the split point $(r.k_m, r.t_m)$ falls on the borders of rectangle. Then r is split into two entries. When we set $c_m = 1$ and $l_m = 1$, the algorithm in Figure 6 is the same with the split algorithm of MVSBT. More details about CMVSBT construction are available in our technical report [2].

Here we prepare a simple example to illustrate the process of entry split in CMVSBT. We assume that we have inserted six points into a compressed MVSBT, as shown in Figure 7(a). The threshold c_m is set to be 6. The max key $r_1.k_m$ is 30 and the max time $r_1.t_m$ is 6. Although the rectangle of r_1 is the whole space, all the points fall in the effective rectangle rec (key range: $[0, k_m]$, time range: $[0, t_m]$). Since $r_1.c \geq 6$, we split it into three rectangles as shown in Figure 7(b). The values of r_1 are not changed since all the points still fall in r_1 . $r_2.v$ is approximated by the number of points covered by the virtual center of r_2 (the red point). As we can see, the red rectangle covers half of rec , so $r_2.v = r_1.c/2 + r_1.v = 3$, $r_3.v = r_1.c/2 = 3$.

For each characteristic set, we need to maintain: (i) the number of distinct subjects and (ii) the number of predicate occurrences. As discussed in next section, each type of statistic values requires two CMVSBTs: one for start points and one for end points. Thus our temporal histogram consists of four CMVSBTs and the schema of characteristic sets. In RDF-TX, we set the max size of temporal histogram as 10% of raw data. If the size of temporal histogram is larger than the threshold, we increase c_m and l_m and merge the neighbor entries until the temporal histogram is small enough.

6.3 Statistics Estimation

Given a query $q(k, t)$, compressed MVSBT estimates the statistics of data records with keys less than k and timestamps smaller than t . The query algorithm consists of two main steps: (i) starting from root node, we look up the CMVSBT nodes whose rectangle covers q ; (ii) in each node, we find all the rectangles whose time range contains t and $k_s \leq k$, and accumulate the approximate statistic value v_a of these rectangles. In a CMVSBT entry, v_a equals to the sum of fixed statistics value v and current statistic value v_e . v_e is approximated by multiplying c by the proportion of query region in the rectangle $ratio$, as $c \times ratio$ where $ratio = ratio_k \times ratio_t$. If $q.k \geq r.k$, $ratio_k = 1$; otherwise, $ratio_k$

Figure 8: (a) Compression Saving for MVBT Index; (b) Index Size Comparison. The size of dictionary is included in the results.

$= (r.k_m - q.k) / (r.k_m - r.k_s)$. And $ratio_t$ can be computed in a similar way.

The query pattern in SPARQL^T is translated to a range query which is not supported by CMVSBT. Thus we use the query reduction approach [40] which reduces one range query into four point queries. In this approach, we need two CMVSBTs for the start points and end points of temporal RDF triples. Then the statistics in the query region (key: $[k_1, k_2]$, time: $[t_1, t_2]$) is calculated as:

$$Q_s(k_2, t_2) - Q_e(k_2, t_1) - Q_s(k_1, t_2) + Q_e(k_1, t_1)$$

where $Q_s(k, t)$ and $Q_e(k, t)$ refer to the point queries on the CMVSBT of start points and end points respectively.

During query optimization, we cache all the statistics to reduce the time on scanning CMVSBTs. When one statistic value is required, we first search the statistics cache. If it is not cached, then we use the CMVSBTs to estimate the statistic value.

7. EXPERIMENTAL EVALUATION

RDF-TX is implemented in Java as a sequential main memory query engine. To evaluate the performance of our system, we conduct experiments on several real world datasets and compare results with alternative approaches.

7.1 Experiment Setup

7.1.1 Dataset

Wikipedia. Wikipedia [4] is a real world dataset extracted from the edit history of English Wikipedia. We parse the raw file and generate 38 million temporal RDF triples as our test benchmark. This dataset contains the history of 1.8 million subjects and 3500 frequent predicates (used in more than 500 triples).

GovTrack. GovTrack [1] is a public dataset that contains the information about congressmen, votes, bills and committees. There are 20 million historical records for 0.4 million subjects and 60 related events (e.g. congressman election or bill voting). We parse the XML source files to temporal RDF triples as our test dataset.

Yago2. Yago2 [18] is a knowledge base derived from Wikipedia, WordNet and GeoNames with more than 30 million temporal RDF triples. Due to space limit and the fact that the evaluation results on Yago2 are very similar to Wikipedia and Govtrack, we leave the results on Yago2 in our technical report.

7.1.2 Implementation and Configuration

RDF Reification. RDF reification provides a way to store RDF triple and its meta knowledge in standard RDF model by representing annotated RDF triple as an entity with following properties: *subject, predicate, object, meta knowledge*. Similarly, we represent a temporal RDF triple as an entity with five properties: *subject, predicate, object, start time, end time*. Then SPARQL^T queries are

easily rewritten to SPARQL queries. We evaluate the reification approach in three well known RDF engines: Jena v2.13 [36], Virtuoso v7.20 [3] and RDF-3X v0.3.8 [27].

RDBMS-based Approach. Temporal RDF triples can be stored in a relational table with five columns *subject, predicate, object, start time, end time*. We choose MySQL memory engine (v5.5) in our evaluation since it supports in-memory B+ tree index. We build four B+ tree indices on SPO, SOP, PSO, OPS and two additional indices on start/end time for evaluation of temporal constraints.

Named Graphs. Named graph [11] is an extension of RDF model that identifies graphs with URLs and allows graph metadata such as provenance and trust. We implement the approach described in [32] that stores temporal information as graph metadata using Jena Named Graph implementation. We also test Ng4j v0.9.3 implementation [9], but it is much slower than Jena and other approaches, so we leave the results on Ng4j in our technical report [2]. In the rest of this paper, we use “Jena Ref” and “Jena NG” to denote Jena Reification and Jena Named Graph respectively.

RDF-TX. Our query engine is a single-thread implementation using compressed MVBT as indices. Only the construction of compressed MVBT is paralleled (using at most four threads).

All the experiments are performed on a machine with 4 AMD Opteron 6376 CPUs (64 cores) and 256GB RAM running Ubuntu 12.04 LTS 64-bit. The index decompression time is included in the query execution time. The execution time reported is calculated by taking the average of 5 runs. The datasets and queries are available in our website [2].

7.2 Index Space

We first investigate the effectiveness of our delta encoding techniques (Section 4.2). We implement the standard MVBT indices (4 indices: SPO, SOP, POS, OPS) with numeric keys as baseline. Figure 8 (a) shows the space costs of standard MVBT and compressed MVBT in Wikipedia dataset. On average, our delta encoding technique reduces the space cost of MVBT by 76%.

Then we compare the space overhead of compressed MVBT and other types of index in Wikipedia, as shown in Figure 8 (b). Since Wikipedia has a large number of unique timestamps, most named graphs are very small (≤ 5 triples). Thus indexing named graph incurs a lot of overhead and Jena Named Graph takes far more space than other approaches. The space cost of MySQL memory engine and Jena Reification are similar, which are 3-4 times of raw data. The index space of our implementation is almost the same with Virtuoso and RDF-3X, while the query performance is much better as shown in Section 7.3. On average, the space of our comprehensive indices (4 compressed MVBT + dictionary) is about 1.8 times of raw data. The results for GovTrack dataset are similar and thus omitted.

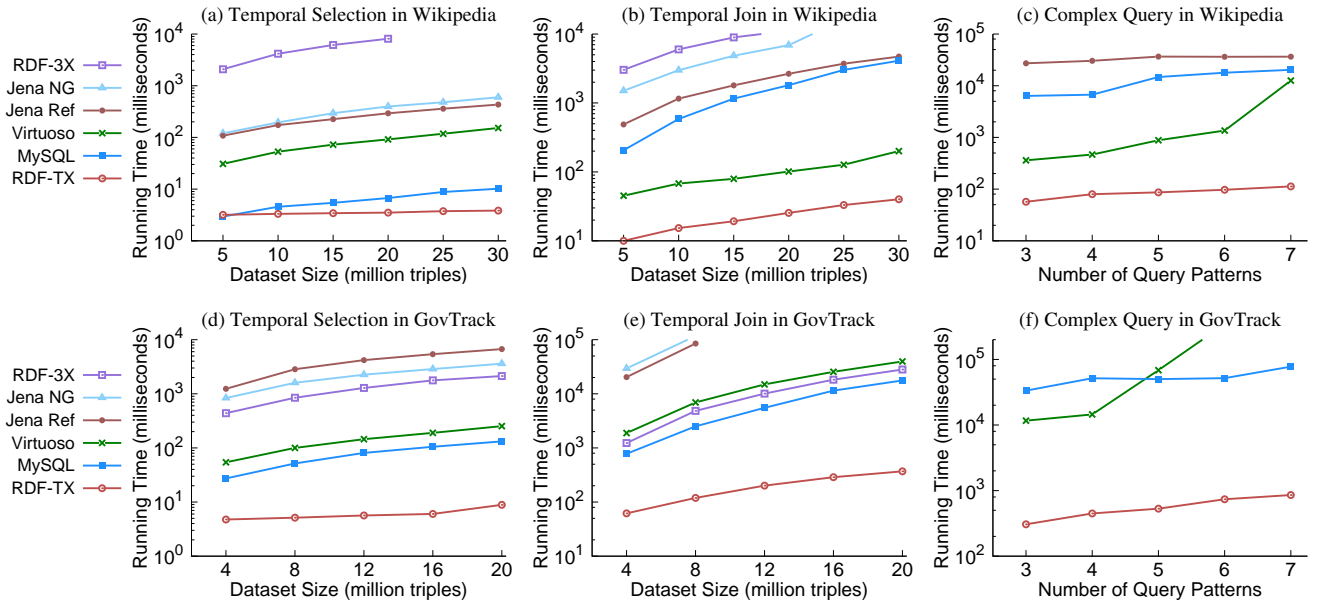

Figure 9: Query Running Time in (a - c) Wikipedia; (d - f) GovTrack.

7.3 Query Performance

To evaluate the query performance of our system, we created three sets of queries: (a) Temporal selection queries, as Example 2 in Section 3; (b) Temporal join queries, as Example 4; (c) Complex queries (2 or more temporal joins). We use the first two query sets to evaluate the performance as the dataset size increases, and the third query set to evaluate the performance as the query pattern size increases. For all the implementations, we report the average warm-cache query execution time.

Temporal Selection and Join. We create 10 temporal selection and 10 temporal join queries for each dataset and conduct the experiments as the size of dataset N increases (N : 5-30 million in Wikipedia and 4-20 million in GovTrack).

Figure 9(a) shows the query execution time for temporal selection in Wikipedia. RDF-TX and MySQL show similar performance in small datasets. As the size of dataset increases, RDF-TX shows better performance than MySQL. In the largest dataset (30 million), RDF-TX is about 3X faster than MySQL and 10X faster than Virtuoso. Jena Named Graph and Reification are 2 orders of magnitude slower than SPARQL³ engine due to the slow index scan.

RDF-3X is much slower than other systems due to its poor support of constraints. Most historical queries involve temporal constraints. For instance, consider Example 2 in Section 3 that searches the budget of University of California in 2013. This query has one temporal constraint that the valid period of temporal RDF triple should overlap (01/01/2013, 12/31/2013). This constraint can be expressed as: $?t_s \leq 12/31/2013 \ \&\& \ ?t_e \geq 01/01/2013$. In RDF-3X, the numbers are encoded as strings. So for temporal constraints, RDF-3X converts strings back to integers at running time to evaluate the constraints, which is inefficient.

The results of temporal join in Wikipedia are shown in Figure 9(b). RDF-TX is about 2 orders of magnitude faster than MySQL and Jena, and 6X faster than Virtuoso. RDF-3X is still slow since the condition of temporal join (e.g. OVERLAP and MEET) is expressed as constraints in FILTER clause.

Figure 9 (d) (e) show the query execution time for temporal selection and join in GovTrack. These approaches take more time to execute since the query patterns (e.g. P and PT) return much more

results in GovTrack due to the reduction of predicates. The RDF-3x performs better than Jena on this dataset since it has a smaller number of distinct time periods (~ 10000) and predicates. MySQL and Virtuoso are about 1 order of magnitude slower than RDF-TX on selection and 2 orders of magnitude slower on Join.

RDF-TX performs 1-2 orders of magnitude faster than most competitors for selection and join. An important reason behind this is that MVBT can process two-dimensional (key and time) range query in one operation, while SPARQL and SQL engines need additional join and index scan.

Complex Queries. We generate 25 complex queries for each dataset with increasing query pattern size (3-7). The generation process is as follows: a set of 5 queries is created initially, and each query has 3 query patterns; then we incrementally add query patterns to existing queries until the size of query patterns reaches 7. The experiment is conducted on two datasets (each has 20 million triples) and the optimizers are enabled in all compared approaches.

The evaluation results in Wikipedia are shown in Figure 9 (c)³. Jena Named Graph and RDF-3X are not reported since they are much slower than other approaches so we omit them. For RDF engine and RDBMS, a query with more patterns is translated to more joins, which increases the complexity of parsing and optimization. On average, RDF-TX is 2 orders of magnitude faster than MySQL and Jena, and 1 order of magnitude faster than Virtuoso.

The evaluation results for GovTrack are shown in Figure 9 (f). A notable change in this graph is that Jena is not reported in this experiment. Jena is too slow compared to other approaches on GovTrack since the query patterns usually cover a large portion of dataset, which leads to slow execution time if an inefficient join order is generated; meanwhile, the column-store traits of Virtuoso excel in this small predicate cardinality case. On average, our system is still about 2 orders of magnitude faster.

7.4 Effectiveness of Query Optimizer

In this section, we explore the impact of query optimizer in the

³The query running time of Virtuoso on pattern size 6/7 is averaged over four queries since Virtuoso generates a very inefficient join order for one query which takes more than 1 hour to finish.

Figure 10: (a) Query Execution Time of the best/worst plans, and the plan generated by SPARQL^T optimizer for complex queries in Wikipedia (b) Index Construction Time (c) Index Maintenance Time

query evaluation. We enumerate all the possible query plans of the complex queries (Section 7.3) in Wikipedia and find the best and worst execution times. Figure 10 (a) shows the query execution times of best/worst plans and the plan generated by RDF-TX query optimizer (blue bar) in a Wikipedia set with 20 million triples. The result shows that the plan generated by our query optimizer is very close to the best performing execution plan. On average, the execution time of optimized query plan is about half of the time used by worst plan. In the relatively simple queries (3 query patterns), the difference between the best plan and the worst plan is small. As the number of query patterns increases, the difference becomes much larger. Thus, the optimizer is important for scaling up towards complex queries with a lot of query patterns. We also measure the time used for query optimization, which varies from 3.5 to 10 milliseconds as the size of query increases.

Then we measure the storage overhead of temporal histogram. The CMVSBTs for temporal statistics are built using the dictionary IDs. As discussed in Section 6.2, we merge CMVSBT entries and increase c_m and l_m until the size is small enough. In this experiment, the size of temporal histogram is 177.5 MB, which is about 8.5% of raw data size.

7.5 Index Construction & Maintenance

For large datasets, we first build standard MVBT and then compress the MVBT indices. In RDF-TX, the process of index construction is paralleled using at most 4 threads. We evaluate the index construction time for compressed MVBT time on different sizes of subsets of Wikipedia in Figure 10 (b) (compression time included). The time for index construction is approximately linear with the size of datasets, and it increases slightly faster in the datasets with 25 million and 30 million triples due to degraded performance caused by JVM garbage collection.

RDF-TX also supports the index update on compressed MVBT, which is important for real-time applications. Thus we further measure the average index maintenance time on a compressed MVBT index built from a 25 million subset of Wikipedia. We perform 1 million updates (68% insert, 32% delete) which simulates the changes in real Wikipedia edit history. Figure 10 (c) shows the results by comparing maintenance time of compressed MVBT with the time used on standard MVBT. Our compression technique shows a decent performance. Comparing with the update on MVBT, the update on compressed MVBT only takes 5% more time. This little overhead is negligible w.r.t. 76% space saved using compression.

8. RELATED WORK

Temporal Index. There has been a large body of research on temporal index in the literature [7, 19, 22, 24, 34]. MAP21 [24] is an index over B+Tree by mapping time ranges to one dimension.

sional points, thus time intervals/points can be used as keys and queried in a B+Tree. OB+tree [34] organizes B+Trees in a versioned way with shared nodes whose contents do not change over versions. However, MAP21 and OB+tree only support single dimension query. BT-tree [19] enables branched versions along with the temporal index, while the time in our system is linear, i.e. no branching. MVBT [7] and TSB-Tree [22] are bi-dimensional indices, which satisfy our requirements exactly. TSB-Tree is a temporal index very similar to MVBT and implemented in Immortal DB [21] on Microsoft SQL Server, with better integration to SQL Server's existing index structures. The major difference between these two is that TSB-Tree migrates old data to a historical store during node splitting, while MVBT moves new data. Since MVBT is a general approach which is not targeted on specific platforms, we adopt and extend it in RDF-TX.

Query Languages and Systems for Temporal RDF. Several query languages [16, 29, 30, 32] have been proposed for temporal RDF triples. T-SPARQL [16] is a temporal extension of SPARQL based on a multi-temporal RDF model. The RDF triple is annotated with a temporal element that represents a set of temporal intervals. Thus a temporal join is expressed using additional functions (e.g. OVERLAP). At the best of our knowledge, no actual implementation of T-SPARQL is available. The τ -SPARQL system reported in [32] uses the temporal RDF model [17] and augments SPARQL query patterns with two variables $?s$ and $?e$ to bind the start time and end time of temporal RDF triples and express temporal queries. The evaluation is done by rewriting τ -SPARQL queries to standard SPARQL queries. Perry et al. [29] propose a framework to support temporal and spatial semantic queries. Simple selection and join queries are expressed using two temporal operators. These operators are implemented in Oracle by extending Oracle Semantic Data Store and SQL functions. These works rely on relational databases/RDF engine to store and query temporal RDF triples, which results in complex SPARQL and SQL queries.

The tRDF system [30] extends the temporal RDF model [17] with indeterminate temporal annotations. The temporal queries are evaluated using tGrin index that clusters the temporal RDF triples based on graphical-temporal distance. However, tRDF only supports a subset of temporal queries discussed in this paper. Most significantly, temporal joins are not supported since tGrin index relies on the temporal distance to filter the triples, while the temporal distance between two temporally joined patterns can not be determined. STUN [20] system supports queries on annotated RDF, but it is not scalable for large temporal datasets.

9. CONCLUSION

In this paper, we present SPARQL^T and its system RDF-TX which supports powerful queries over the history of knowledge bases.

SPARQL^T enables the expression of a wide variety of temporal queries via simple extension of SPARQL graph patterns and built-in functions. SPARQL^T queries are efficiently evaluated in the backend query engine that achieves excellent performance by exploiting M-VBT as index and leveraging fast algorithms for range selection and temporal join. RDF-TX also features a query optimizer that uses the statistics of temporal RDF graphs to find the efficient join orders for complex SPARQL^T queries. Extensive experiments on real world datasets show that RDF-TX outperforms other approaches that use state-of-art RDF engines and relational databases in all kinds of queries and delivers 1 - 2 orders of magnitude performance improvement in complex queries. This confirms the effectiveness and superior performance of RDF-TX.

ABSTRACT

Multidimensional data are published in the web of data under common directives, such as the Resource Description Framework (RDF). The increasing volume and diversity of these data pose the challenge of finding relations between them in a most efficient and accurate way, by taking into advantage their overlapping schemes. In this paper we define two types of relationships between multidimensional RDF data, and we propose algorithms for efficient and scalable computation of these relationships. Specifically, we define the notions of *containment* and *complementarity* between points in multidimensional dataspace, as different aspects of relatedness, and we propose a baseline method for computing them, as well as two alternative methods that target speed and scalability. We provide an experimental evaluation over real-world and synthetic datasets and we compare our approach to a SPARQL-based and a rule-based alternative, which prove to be inefficient for increasing input sizes.

Keywords

RDF, Multidimensional Data, OLAP, Information Extraction, Algorithms, Performance

1. INTRODUCTION

Over the past few years, a wide range of public and private bodies such as statistical authorities, academic institutions, financial organizations and pharmaceutical companies adopt RDF and the Linked Data (LD) paradigm [9, 31] to enable

public access to multidimensional data in a variety of domains, including socio-economics, demographics, enterprise OLAP, clinical trials and health data. The published data enables third parties to combine information, perform analytics over different datasets and gain insights to assist data journalism, industry data management, and evidence-based policy making [25, 4, 27].

Multidimensional data are usually treated under the OLAP prism, where they are represented as *observations* that are instantiated over pre-defined *dimensions* and *measures* [7]. The dimensions provide context to the measures and are structured in hierarchies of different granularity *levels*. For example, a dataset that measures population broken down by locations and time periods, will consist of two dimensions, namely *location* and *time-period*, pertaining to granularity levels, such as countries, regions, and cities, or decades, years and quarters, respectively. A combination of fixed dimension levels is referred to as a *cube*; it contains the set of observations that instantiate these levels, such as the *populations of EU countries in the last decade*, or the *unemployment of EU cities in 2014*. All different combinations of dimension levels form a hierarchical cube *lattice*, where cubes are related with ancestry links.

In the context of Linked Data, the modelling recommendation is the Data Cube Vocabulary (QB) [9]. This provides a common meta-schema for mapping multidimensional data to RDF, enabling the representation of datasets, dataset schemas, dimensions, dimension hierarchies (e.g. codelists), measures, observations and slices (parts of datasets). An example observation can be seen in Listing 1, in which observation *obs1* measures the population of Germany in 2001. The values for 2001 (ex:Y2001) and Germany (ex:DE) are URIs from an example code list. The reuse of common URIs for handling multidimensional elements across different sources enables sharing of terms and the use of SPARQL for federating queries over remote datasets, laying the basis for the application of OLAP analytics at web scale.

Currently, there are few works on definitions and techniques for the discovery and classification of relationships between multidimensional observations in RDF settings [18, 32]. Such relationships can provide useful information to the analyst, such as whether an observation contains aggregated data with respect to other observations, and when two ob-

servations measuring different phenomena are complementary and can be combined. Assume that a data journalist is working on the issue of unemployment in different parts of the world and wants to explore whether unemployment rates relate to the population of a city or a country. Assume now that our journalist obtains dozens of datasets on the topic from various sources and wants to see whether and how they can be combined to facilitate his task. Although the journalist has defined his own reference dimension hierarchies¹ as shown in Figure 1, and converted the incoming data values to them via a simple script, it is still unclear to him that among the dozens of datasets he has collected (D_1 , D_2 and D_3 of Figure 2), coming from different RDF sources, can be combined to support his task.

In our example, observation o_{11} shares the same dimension values with o_{31} , but they measure two different facts, which can be complemented. Furthermore, observations o_{21} , o_{22} that measure unemployment for 2011 in Greece and Italy, respectively, contain observations o_{32} , o_{33} that measure unemployment in Athens and Rome for a sub-period of the same year, although o_{21} , o_{22} measure poverty as well. The resulting table can be seen in Figure 3. This knowledge gives insights on how observations are related across datasets, how OLAP operations (roll-ups, drill-downs) can be applied in order to navigate and explore remote cubes, make observations comparable, provide recommendations for online browsing and quantify the degree of relatedness between data sources. Furthermore, materialization of these relationships helps speed up online exploration, and computation of k-dominance as defined in [6], and skylines or k-dominant skylines. Especially in the case of skylines, computation of containment between observations provides a means to directly access skyline, or k-dominant skyline points in collections of large web data.

However, placing different data into the same context and finding hidden knowledge is difficult and computationally challenging [4]. The detection of pair-wise relationships between observations is inherently a quadratic task; typically every observation from one dataset must be compared to all others within the same or from different datasets. The use of traditional ways such as SPARQL- or rule-based techniques becomes inefficient as the number of observations and the number of cubes increases. Our preliminary experiments employing recursive SPARQL queries with property paths and negation, indicate that even for 20k observations from 7 datasets it can take more than one hour to complete in commodity hardware, while the same tasks time-out for larger numbers of instances. The same holds when inference-based techniques are used: OWL-based reasoning lacks the expressivity for complex property-based inference, while rule-based reasoning such as SWRL [15] and Jena Rules [5] does not scale adequately due to the transitive nature of the relationships and the universal quantification needed to encode the conditions; the search space expands exponentially [12]. From the above, there is a clear need for establishing new efficient methods for computing pair-wise relationships be-

¹In realistic settings, schema alignment is often necessary. Two prominent cases where it is used in practice include: (a) traditional BI environments, where all dimensions provide a reconciled *dimension bus*, and (b) user-initiated data collections from the web. In both cases, incoming data have to be translated to a reference vocabulary, *before* being used for further analysis.

tween RDF observations that can scale up to the numbers and variety of datasets currently published on the web of data.

Approach Overview. In this paper, *we address the problem of efficiently computing containment and complementarity between RDF observations*, extending the preliminary work presented in [22]. Specifically, given an observation o_g , and a set of observations O from different sources, we define two relationships, namely *containment* and *complementarity*. A *containment* relationship captures whether an observation contains aggregated information with respect to other observations. It determines if values from the dimensions of o_g contain fully or partially values of the dimensions of another observation, thus enabling rollup and drilldown operations, directly or indirectly, as well as assigning them a hierarchy-based similarity metric. A complementarity relationship captures whether the measures of two observations can be combined together, providing comparable data for the same points in the multidimensional space. More specifically, we extend the notion of schema complement, defined in [10] and apply it at the instance level to discover complementary observations.

We first present a $O(n^2)$ baseline technique to calculate these properties. Then, we introduce two alternatives that prove to be more efficient and scalable in terms of computation time. The first performs observation *clustering* and limits comparisons between observations in the same clusters. The second uses a *multidimensional lattice* to assign observations to specific permutations of dimensions and levels, and prune the search space by checking for restrictions at the schema-level. We experimentally evaluate these 3 techniques over a set of 7 real-world multidimensional datasets and compare them in terms of efficiency with traditional techniques, namely with a SPARQL-based and a rule-based approach. Finally, we evaluate the scalability of our approach in an artificially generated dataset.

Contributions. The contributions of this paper can be summarized as follows:

- we extend the notions of *full* and *partial containment* between two observations defined in [22] as derivatives of the hierarchical relationships between their dimension values, and observation *complementarity* as a

The remainder of this paper is organized as follows. Section 2 presents preliminaries and formulates the problem of containment and complementarity computation between RDF cubes. Section 3 presents the baseline algorithm and two proposed improvements for computing the defined relationships. Section 4 describes the performed experiments and evaluation. Finally, section 5 discusses related work and section 6 concludes this paper.

2. PRELIMINARIES

The problem space is composed of n datasets, each of which contains a number of observations, structured in one or more cubes. A single dataset is composed of the schema part (i.e. dimensions, measures and attributes), and the data part (i.e. observations or facts). Dimension values are provided by code lists with hierarchical structure, whereas flat code lists pertain to dimensions with exactly one level.

Definition 1 (Dataset Structure): Let $D = \{D_1, \dots, D_n\}$ be the set of all input datasets. A dataset $D_i \in D$ is composed by the set of observations, O_i , and the set of schema definitions, S_i , and $O = \{O_1, \dots, O_n\}$ and $S = \{S_1, \dots, S_n\}$ are the sets of all observations and schema definitions in D . Furthermore, a schema S_i consists of the sets of dimensions P_i and measures M_i defined in D_i , i.e., $S_i = \{P_i, M_i\}$. Let $P = \bigcup_{i=1}^n P_i = p_1, p_2, \dots, p_k$ and $M = \bigcup_{i=1}^n M_i = m_1, m_2, \dots, m_l$ be the set of all k distinct dimensions and l measure properties in D . Any $p_j \in P, m_j \in M$ can belong to more than one

S_i , as dimension and measure properties are reused among sources. In our example, S_1 , S_2 and S_3 are the schemata of datasets D_1 , D_2 and D_3 , and dimensions $refArea$ and $refPeriod$ belong to all three schemata. Similarly, measure $ex:unemployment$ belongs to both M_2 and M_3 . An observation $o \in O_i$ is an entity that instantiates all dimension and measure properties defined in S_i . The value that observation o_i has for dimension p_j is h_{ij}^j . In the example, the values in the white cells represent dimension values (e.g. "Athens" is a value for dimension $refArea$), while grey cells represent measured values (e.g. 10% unemployment).

Definition 2 (Hierarchies): Each dimension $p_j \in P$ takes values from a code list, i.e. a set of fixed values coded by URIs, $C(p_j) = \{c(p_j)_1, \dots, c(p_j)_m\}, j = 1 \dots k$, (for simplicity we write c_{ji} instead of $c(p_j)_i$). Each code list defines a hierarchy such that when $c_{ji} \succ c_{jm}$, then c_{ji} is an ancestor of c_{jm} . Furthermore, we define c_{jroot} as the top concept in the code list of p_j , i.e., an ancestor of all other terms in the coded list, such that $\forall c_{ji} : c_{jroot} \succ c_{ji}$. This kind of ancestry is reflexive, i.e. $\forall c_{ji} : c_{ji} \succ c_{ji}$. In Figure 2, sample code lists are depicted for the three dimensions shown in Figure 1. In our example, $Greece \succ Athens$, $Ioannina$ and $Italy \succ Rome$.

A *complementarity* relationship captures whether two observations measure different facts about the same set of dimension instances. In the motivating example of Figure 1, o_{11} and o_{31} are complementary because they measure different facts (population and unemployment respectively) about the city of Athens in 2001. The fact that o_{11} refers to all values from the sex dimension does not provide any further specialization and is inherently found in o_{31} as well. This is captured in the following definition.

Definition 3 (Observation Complement): Given two observations o_a and o_b and their dimensions P_a and P_b , o_a complements o_b when the following conditions hold:

$$\forall p_i \in P_a \cap P_b : h_{ai}^i = h_{bi}^i \quad (1)$$

$$\forall p_j \in P_b \setminus P_a : h_{bj}^j = c_{jroot} \quad (2)$$

Therefore, $(1) \wedge (2) \Rightarrow Compl(o_a, o_b)$. We denote this with $Compl(o_a, o_b)$. Definition 1 states that the shared dimensions must have the same values as stated in (1), and all other dimension values of o_b must be equal to the root of the dimension hierarchy, providing no further specialization, as stated in (2). For example, an observation measuring poverty in Greece is observation complement with an observation measuring the population in Greece for all human genders. In our example, observations o_{11} and o_{31} are complementary, in that they measure different things for Athens in 2001. Condition (2) holds for o_{31} in the sex dimension, where absence of the dimension implies existence of the root value c_{jroot} (i.e. no specialization).

A *containment* relationship captures whether an observation aggregates the measures of the contained observations. For example, measuring the population of Greece implicitly contains all the populations of Greece’s sub-regions. We distinguish between *full* and *partial* containment. The former denotes that all contained observations must be aggregated (e.g., a roll-up operation) for being observation complement with the containing one, while the latter denotes that both contained and containing observation must be rolled-up on their disjoint dimensions for becoming complementary. These two concepts are defined as follows.

Definition 4 (Partial and full containment): Given two observations o_a and o_b , their dimensions P_a and P_b and their measures M_a and M_b , partial containment between o_a and o_b exists when the following conditions hold:

$$M_a \cap M_b \neq \emptyset \quad (3)$$

$$\exists p_i \in P_a \cap P_b : h_a^i \succ h_b^i \quad (4)$$

Therefore, $(3) \wedge (4) \Rightarrow Cont_{partial}(o_a, o_b)$. An observation o_a partly contains o_b when there is at least one M_i shared between o_a and o_b as stated in (3), and there exists at least one dimension whose value for o_a is a hierarchical ancestor of the value of the same dimension in o_b , as stated in (4). We denote this as $Cont_{partial}(o_a, o_b)$. In the example, observation o_{21} partially contains o_{31} , because *Greece* contains *Athens* but *2001* does not contain *2011*. By rolling up on the *refPeriod* dimension, the two observations become complementary.

Similarly, full containment between o_a and o_b exists when the same preconditions (3)-(4) hold along with a universal restriction on (4) for all dimension values, i.e:

$$\forall p_i \in P_a \cap P_b : h_a^i \succ h_b^i \quad (5)$$

Therefore, $(3) \wedge (4) \wedge (5) \Rightarrow Cont_{full}(o_a, o_b)$. An observation o_a fully contains o_b when there is one M_i shared between o_a and o_b as stated in (3), and values of all dimensions for o_a are hierarchical ancestors of the values for the same dimensions in o_b as stated existentially in (4) and universally in (5). We denote this with $Cont_{full}(o_a, o_b)$. Observe that the containment property is not symmetric and that given $Cont_{full}(o_a, o_b)$, then $Cont_{full}(o_b, o_a)$ is not implied. In the example, o_{21} fully contains o_{32} and o_{34} . The notation is summarized in Table 1. Based on the above, our problem is formulated as follows.

Problem: Given a set D of source dataset, and a set O of observations in D , for each pair of observations $o_i, o_j \in O, i \neq j$, assess whether a) $Cont_{full}(o_i, o_j)$, b) $Cont_{partial}(o_i, o_j)$ and c) $Compl(o_i, o_j)$. In the following section, we provide our techniques for computing these properties.

Table 1: Notation

Notation	Description
o_i	The i-th observation in a set O
P_i	The set of dimensions for observation o_i
p_i	The i-th dimension in a set P_k
M_i	The set of measures for observation o_i
h_a^i	Value of dimension p_i for observation o_a
$h_a^i \succ h_b^i$	h_a^i is a parent of h_b^i
c_{jroot}	The root value (ALL) for dimension p_j
$Compl(o_a, o_b)$	Observation o_a complements o_b
$Cont_{full}(o_a, o_b)$	Observation o_a fully contains o_b
$Cont_{partial}(o_a, o_b)$	Observation o_a partially contains o_b

3. ALGORITHMS

In this section, we present three approaches for computing containment and complementarity relationships. We first present a baseline method of $O(n^2)$ complexity and then we propose two alternatives in order to achieve scalable and fast solutions.

3.1 Baseline

Our *baseline* algorithm performs pair-wise computations between all pairs of observations in a given data space. To achieve this, we model observations as bit vectors in a multidimensional data space represented by an occurrence matrix \mathbf{OM} , where rows represent observations and columns are values in their dimensions as well as ancestor values in their dimension hierarchies. \mathbf{OM} encodes the occurrence of a dimension value in an observation as well as the hierarchy in which this value belongs to, by setting the value of 1 to all columns that are ancestors of this value.

Dimension alignment is often required to take place before this step, in order to have a reconciled dimension bus in the feature space. As discussed later on in the experiments section, we employ a state-of-the-art tool for performing the interlinking of dimension values across different datasets. Note that this procedure is orthogonal to the work presented in this paper. The problem of dimension alignment, and record linkage in general, is a separate research problem and is not underestimated; however, (a) data conversion is feasible and amortized over time (esp., if data collection from "favorite" sources is recurring), and (b) the focus of this paper is on analytics and not data integration.

Constructing the Occurrence Matrix. Each observation o_i defines a bit vector \mathbf{o}_i and all $\mathbf{o}_i \in O$ comprise the occurrence matrix \mathbf{OM} of $|O| \times |C|$ dimensions, defined by the occurrences of code list values in the respective dimensions. Each value $c_{ji} \in C_j$ corresponding to dimension p_j is a feature, i.e., a column in \mathbf{OM} . Hierarchical containment is encoded into \mathbf{OM} using a bottom-up algorithm that assigns a value of 1 in column c_{ji} and all of its parents, if the value h_a^j of the dimension p_j of o_a is equal to the feature c_{ji} . Finally, we set the c_{jroot} columns of all observations that do not contain p_j in their schema. This means that dimensions not appearing in a schema are mapped to the *top* concept (i.e. root term), including all possible values.

Matrix \mathbf{OM} can be further broken down in separate sub-matrices for each code list, i.e., $\mathbf{OM} = [\mathbf{OM}_1, \dots, \mathbf{OM}_{|C|}]$ for all dimensions, where \mathbf{OM}_i is a sub-matrix that represents occurrences for all values of dimension p_i . Matrix \mathbf{OM} for the example of Figure 2, given the hierarchies shown in Figure 1, is shown in Table 2. \mathbf{OM} is used as an input for our algorithm that computes a containment matrix. The latter is used for assessing both complementarity and containment

properties.

Computation of containment. A containment matrix \mathbf{CM}_i captures pair-wise containment between observations, for dimension p_i . If a cell $\mathbf{CM}_i[a, b] > 0$, then o_a and o_b are related via containment for p_i . To compute \mathbf{CM}_i , we apply a conditional function between pairs of rows, as bit vectors. Containment exists if the logical AND operation between the bit vectors of the rows returns one of the two bit vectors. We define this check as the following conditional function applied on o_a and o_b :

$$sf(o_a, o_b) |_{(p_i)} = \begin{cases} 1, & \text{if } a \wedge b = b \\ 0, & \text{otherwise} \end{cases}$$

Notice that we apply sf for o_a and o_b for dimension p_i in \mathbf{OM}_i . Application of this function for each dimension returns a set of $|P|$ containment matrices, $\mathbf{CM}_1, \dots, \mathbf{CM}_k$. By adding these we get the *Overall Containment Matrix* \mathbf{OCM} :

$$\mathbf{OCM} = \frac{\sum_{i=1}^k u_i \mathbf{CM}_i}{\sum_{i=1}^k u_i}$$

\mathbf{OCM} values are normalized; we derive *full containment* when a cell has a value of 1, and *partial containment* when a cell has a value between 0 and 1 (non-inclusive). To assert which particular dimensions exhibit containment in a partial relationship, we examine the cells in \mathbf{CM}_i being equal to 1. The occurrence of a 0 value indicates that full containment and complementarity can not hold. Note also that measure overlaps can be easily detected with a simple lookup. The construction of the \mathbf{OCM} matrix is explained in Algorithm 1 *computeOCM*. We then calculate containment and complementarity using the \mathbf{OCM} -based Algorithm 2 *baseline*.

Computation of complementarity. Following the definition of observation complementarity, and given that the non-appearing values are set to c_{jroot} , we use \mathbf{OCM} to assess whether a pair of observations exhibits full containment in both directions, i.e. $Cont_{full}(o_a, o_b)$ and at the same time $Cont_{full}(o_b, o_a)$.

Analysis. The baseline algorithm has $\Theta(n^2)$ time complexity for n observations, because it visits each pair of observations exactly once, if all three types of relationships are to be retrieved. The occurrence matrix \mathbf{OM} requires $\Theta(nk)$ space for n observations and k features, given a simple array implementation. However, for large k the matrix tends to become sparse, therefore a sparse matrix implementation would yield a significant decrease in the required space. In practice, if at least one 0 is found in the \mathbf{CM} matrices, the pair under comparison is no longer candidate for either full containment or complementarity. We keep this in an index table to avoid meaningless comparisons in the next step, if only full containment or complementarity is to be computed. Finally, if we are not interested in identifying the particular dimensions that exhibit containment in a partial containment relationship, we skip iterating through the \mathbf{CM}_i matrices and identifying the zero values, and just keep the value as a metric of the degree of partial containment that the pair exhibits.

3.2 Computation with Clustering

The baseline algorithm becomes inefficient for large datasets and does not scale due to its quadratic complexity. For this reason, we improve its performance by applying a pre-processing step that prunes the search space by limiting

Algorithm 1 *computeOCM*

Input: An occurrence matrix \mathbf{OM} with N rows and $|C|$ columns, a set P of dimensions and their start indices in \mathbf{OM}

Output: A $N \times N$ overall containment matrix \mathbf{OCM}

```

1: initialize  $\mathbf{OCM}[] []$ 
2: for each  $p_i \in P$  do
3:   initialize  $\mathbf{CM}_{p_i}[] []$   $\triangleright$  one containment matrix per dimension
4:   for each  $o_j \in \mathbf{OM}_{p_i}$  do  $\triangleright p_i$  defines a start index
5:     for each  $o_k \in \mathbf{OM}_{p_i}$  do
6:       if  $o_j \text{ AND } o_k == o_j$  then
7:          $\mathbf{CM}_{p_i}[j][k] \leftarrow 1$ 
8:       else
9:          $\mathbf{CM}_{p_i}[j][k] \leftarrow 0$ 
10:     $\mathbf{OCM}[j][k] \leftarrow \mathbf{OCM}[j][k] + (\mathbf{CM}_{p_i}) / |P|$   $\triangleright$ 
    normalize for # of dimensions
11: return  $\mathbf{OCM}$ 
```

Algorithm 2 *baseline*

Input: A $N \times N$ overall containment matrix \mathbf{OCM} .

Output: S_F, S_P, S_C sets of fully, partial containment and complementarity relationships, and optionally a map of partial containment relationships map_P with the dimensions they exhibit containment in.

```

1: initialize  $S_F, S_P, S_C$ 
2: for each  $o_i \in \mathbf{OCM}$  do
3:   for each  $o_j \in \mathbf{OCM} \ \&\& \ o_j \neq o_i$  do
4:     if  $\mathbf{OCM}[i][j] == 1$  then
5:        $S_F = S_F \cup (o_i, o_j)$ 
6:       if  $\mathbf{OCM}[j][i] == 1$  then
7:          $S_C = S_C \cup (o_i, o_j)$

comparisons. Algorithm 3 presents our approach. It takes as input the occurrence matrix containing the bit vectors for the observations and applies a clustering algorithm that splits the matrix into smaller occurrence matrices. It then applies the *computeOCM* and *baseline* algorithms to each separate cluster. This way comparisons between pairs of observations are limited within each cluster. This is shown in Algorithm 3.

Clustering configuration. In order to compute clusters, state-of-the-art clustering algorithms can be employed. We have experimented with k/x-means [26], bottom-up hierarchical clustering and fast canopy clustering [21] for the purposes of evaluating our algorithms. To avoid introducing extra time overhead in the containment and complementarity computation stage, we approximate the algorithm by clustering a sample of the data and assigning the remaining points to the identified clusters.

Analysis. Time and space complexity of the clustering step depends on the complexity of the chosen clustering algorithm, the number of clusters and the distribution of observations in the clusters. The baseline algorithm will run times equal to the number k of clusters. However, the dis-

Algorithm 3 *clustering*

Input: An occurrence matrix **OM** with N rows and $|C|$ columns.

Output: S_F, S_P, S_C sets for fully, partial containment and complementarity relationships.

```

1: clusters[] ← cluster(OM, ...)           ▷ e.g. k-means
2: initialize OCM ← 0
3: for i = 1 to clusters.size do
4:   OCMi ← computeOCM(clusters[i], P)
5:   SFi, SPi, SCi ← baseline(OCMi)
6:   SF, SP, SC ← (SF, SP, SC) ∪ (SFi, SPi, SCi)
return SF, SP, SC

```

tribution of observations in clusters is not known for a given collection of datasets. In the centroid-based case (canopy, k/x-means), assuming an equal distribution of $\frac{n}{k}$ observations per cluster, then the time complexity for each cluster is $\Theta(\frac{n}{k})^2$ thus making the total time complexity $\Theta(\frac{n^2}{k})$. Following a rule of thumb where $k = \sqrt{\frac{n}{2}}$, this becomes $\Theta(n^{1.5})$, at the cost of information loss, as will be shown in the experiments.

3.3 Computation with Cube Masking

The efficiency achieved by the clustering approach can result in lower recall levels as observations that are likely to be related might end up in different clusters. In this section, we propose a scalable algorithm that greatly increases speed and at the same time maintains 100% recall. The approach is based on the hierarchical characteristics of the dimension values. We first construct a lattice of all possible level combinations for all the dimension values that appear at least once in the input. Then, we map all observations to their respective lattice nodes (i.e. cubes) and check if the lattice nodes, rather than the observations, meet the containment and complementarity criteria. If so, comparisons need only be performed between observations belonging to these lattice nodes. To demonstrate this further, consider the lattice shown in Figure 3 that corresponds to the dimension hierarchies of Figure 2. Each node corresponds to a combination of the levels of all dimensions. Therefore, node "210" repre-

sents the cube of all observations that pertain to values at level 2 for *refArea*, level 1 for *refPeriod* and level 0 for *sex*. In the cases of full containment and complementarity, we do not need to compare observations that belong to lattice nodes that are not hierarchically related, such as node "121" with node "311". In the case of partial containment we look for at least one dimension inclusion (i.e. path) in the lattice before comparing the contents.

Based on these observations, we propose the *cubeMasking* algorithm (Algorithm 4) that works in the following steps: i) It first identifies cubes in the input datasets and populate the lattice; ii) it maps observations to cubes; iii) it iterates through cubes and does a pair-wise check for the containment criterion and finally iv) it compares observations between pairs of cubes that fulfils this criterion. In order to perform these steps, we use a hash table to ensure that a value's level can be checked in constant time. We then go on to identify the cubes and build the lattice by iterating through all observations and extracting their unique combinations of dimensions and levels. To do so, we apply a hash function on each observation that both identifies and populates its cube at the same step. Finally, we iterate through the identified cubes and by doing a pair-wise check for the containment and complementarity criteria, all meaningful observation comparisons are identified. This can be seen in Algorithm 4.

Analysis. Instance-level comparisons are limited between pairs of comparable cubes that are identified by the algorithm. At worst, the maximum number of cubes for a set of input datasets is the number of permutations of dimensions and levels, i.e. $k^{(|P|)}$, where k is the maximum level of all hierarchies and $|P|$ is the number of dimensions. Checking for potentially comparable pairs of cubes costs $O(k^{(2|P|)})$ in the worst case, but for an average of $bk^{(|P|)}$ present cubes in the input, and $abk^{(|P|)}$ number of comparable cubes, where a and b are constants between 0 and 1, the algorithm will require ab^2n^2 comparisons instead of n^2 .

4. PERFORMANCE EVALUATION

Datasets. We have experimented with seven real-world datasets taken from the statistics domain. Eurostat Linked

it is relevant only to the *clustering* algorithm, as the *baseline* and the *cubeMasking* algorithms achieve 100% recall. Note, also, that the precision is 100% for all algorithms as a derivative of the determinism in the relationship definitions. In order to derive recall, we have compared the output of the *clustering* method with the ground truth taken from the *baseline* output. Note that we do not consider any decrease in recall induced by the tool used in the dimension alignment step. Since the recall of our approach is not dependent to the result of the alignment process, we assume that the output of the linking tool (in our case LIMES) achieves 100% recall correctly matching schema elements and dimension values across all datasets.

Experimental Setting. Our approach was implemented in Java 1.7, and all experiments were performed on a server with Intel i7 3820 3.6GHz, running Debian with kernel version 3.2.0 and allocated memory of 16GB. We implemented the approaches and performed a series of comparisons between them, starting from an input size of 2k observations, over the original fixed size of dimensions. We continued the experiment with an input size of 20k and then we further increased it with a 20k step. For the *clustering* method, we have experimented with canopy clustering, hierarchical clustering and x-means, all applied on a 10% random sample of the original datasets and empirical studies showed that x-means outperformed the other two methods greatly in terms of recall achieved in comparable time frames. Based on the bit-vector approach, we used the Jaccard coefficient as a similarity metric for our binary feature space. The *cubeMasking* algorithm has been further optimized to limit the number of cube comparisons by storing for each cube, the full set of its children in memory.

SPARQL-based. We have experimented with SPARQL queries over a Virtuoso 7.1 instance for computing the relationships. Note that universal quantification as well as recursive querying (i.e. property paths) are necessary to compute full containment and complementarity. Property paths are directly supported by SPARQL 1.1, however, universal quantification must be mimicked by using a negation construct that includes a nested recursion, which makes the queries costly. Furthermore, occurrence of partial containment can be detected by SPARQL queries easily, but it is complicated and costly to quantify it. The SPARQL approach is composed of three SPARQL queries; for simplicity, we are only interested in detecting the underlying *existence* of the containment and complementarity relationships, and we do not quantify it like in the computation of the OCM matrix. In the case of *partial containment*, the query for detecting pairs of observations is as follows:

```
SELECT DISTINCT ?o1, ?o2
```

```
WHERE {
  ?o1 a qb:Observation .
  ?o2 a qb:Observation .
  ?o1 ?d1 ?v1 .
  ?o2 ?d1 ?v2 .
  ?v1 skos:broaderTransitive/skos:
    broaderTransitive* ?v2
  FILTER(?o1 != ?o2)
}
```

The above query will select pairs of *?o1* and *?o2* that have at least one dimension with ancestral values; *?v1* must be a parent of *?v2*. The above query does not provide the number of dimensions that participate in the *partial containment*; this would make the query more complicated. In the case of *complementarity*, we tested the data against the following SPARQL query:

```
SELECT ?o1, ?o2
WHERE {
  ?o1 a qb:Observation .
  ?o2 a qb:Observation .
  FILTER NOT EXISTS {
    ?o1 ?d1 ?v1 .
    ?o2 ?d1 ?v2 .
    FILTER(?v1 != ?v2)
  }
  FILTER(?o1 != ?o2)
}
```

The query will be matched against pairs of observations whose shared dimensions do not have different values. In both queries, we have relaxed the conditions presented in section 2 regarding the observations' schema.

Rule-based. The rule-based approach consists of three forward-chaining rules implemented in Jena, as the Jena generic rule reasoner is simple to use and offers the required expressivity. The rule for computing *full containment* is as follows:

```
observation(o1) ^ observation(o2)
^ (o1 != o2)
^ ∃p.(has_dimension_value(o1,p,v1)
  ^ has_dimension_value(o2,p,v2)
  ^ is_ancestor(v1,v2))
^ ∀p.( has_dimension_value(o1,p,v1)
  ^ has_dimension_value(o2,p,v2)
  ^ is_ancestor(v1,v2))
⇒ full_containment(o1,o2)
```

In essence, we are checking for pairs of different observations that exhibit both existential and universal quantification in having dimension values subsume each other. The existential quantification is needed to ensure that there exists at least one such relationship, while the universal is needed to ensure that all relationships hold true. Similarly, the rule for *partial containment* checks the existential restriction; that

is, we need at least one pair of dimension values to exhibit a containment relationship between o_1 and o_2 . Therefore, the rule is as follows:

```
observation(o1) ∧ observation(o2)
∧ (o1 ≠ o2)
∧ ∃p.(has_dimension_value(o1,p,v)
    ∧ has_dimension_value(o2,p,v))
⇒ partial_containment(o1,o2)
```

The rule for *complementarity* is activated when two different observations have the same values for all of their shared dimensions and is summarized in the following:

```
observation(o1) ∧ observation(o2)
∧ (o1 ≠ o2)
∧ ∃p.(has_dimension_value(o1,p,v)
    ∧ has_dimension_value(o2,p,v))
∧ ∀p.(has_dimension_value(o1,p,v)
    ∧ has_dimension_value(o2,p,v))
⇒ complement(o1,o2)
```

All datasets along with the experiment code are available online at <http://github.com/mmeimaris>.

4.1 Experimental Results

Our experiments indicate that the quadratic *baseline* algorithm is improved substantially by our two proposed alternative methods, i.e. *clustering* and *cubeMasking*. Specifically, we have achieved improvement by roughly one order of magnitude for the computation of *full containment* and *complementarity* by using the *cubeMasking* algorithm, while we find that the *clustering* algorithm exhibits a trade-off between execution time and relationship recall. The results can be seen in Figure 5.

Baseline. The *baseline* behaves as expected, performing n^2 comparisons for n observations. The partial containment relationships are quantified with a value between 0 and 1, non-inclusive, which increases monotonically in proportion with the number of dimensions that a pair of observations exhibits containment in. The results for computing the relationships can be seen in Figure 5(a-c). However, as can be seen in the Figure, it is cheaper to compute only full containment and complementarity because the cases where these do not apply can quickly be ruled out in the *computeOCM* step. This approach does not scale with respect to input size, as all pairs of rows in the *OCM* matrix, representing observations, have to be visited in order to detect and quantify containment and complementarity. It should be noted that, when having computed full containment, complementarity can be detected a posteriori by iterating through the fully contained pairs and checking for mutual (i.e. bi-directional) full containment.

Clustering. In the case of *clustering*, we have experimented with three different clustering algorithms, one agglomerative and two centroid-based, namely *hierarchical*, *canopy* and *x-means* respectively. Figure 5(d) shows the recall levels of the three algorithms. We have found that *x-means*, even when applied to a random 10% sample of the data, outperforms the other two in the resulting recall. Overall, the clustering method shows promising results and leaves room for improvement as far as the clustering step is concerned. Note that by definition, the *baseline* algorithm is equivalent to *clustering* with exactly one cluster. A large number of clusters k will limit the total number of comparisons, and consequently make the computations faster, but

the process will be lossy, ultimately achieving lower recall levels.

Cube Masking. The *cubeMasking* algorithm is the fastest of all the approaches we experimented with, mainly because of the linear cost of identifying and assigning observations to cubes, and the reduced number of performed comparisons. This is a consequence of the fact that it takes advantage of the distributions of dimension levels and values, and reduces the needed comparisons to a minimum with respect to the baseline and clustering algorithms, while maintaining full recall. Furthermore, the experiments on synthetic data, as well as the observation that the ratio of cubes per input size tends to decrease as input size increases as depicted in Figure 5(f), show that it is scalable for big datasets. In essence, Figure 5(f) shows that the number of cubes in a collection of datasets will increase in a lower rate than the number of input observations. This implies that as the input size increases, the *cubeMasking* algorithm will usually not result in intractable pair-wise comparisons.

With *cubeMasking*, we need to check for parent-child relationships between cubes. The brute-force way to achieve this is to iterate through all pairs of cubes and check for pair-wise ancestry. This ancestry exists when all dimension levels of the first cube are equal or less than their respective dimension levels of the second cube. By pre-fetching and storing all children of each cube in memory, we introduce a conditional optimization that yields roughly 15-20% faster execution time for any input size as can be seen in Figure 5(g). However, creating this mapping implies either an explicit iteration of all cubes, which is costly, or an unavoidable iteration for one of the relationship types, which can be taken advantage of for the other two. Furthermore, keeping a list with the children of any given cube node adds an extra memory overhead, however in this work we are not interested in the memory footprint of each method.

SPARQL and Rule-based. These approaches perform adequately for small inputs, as shown in Figure 5(a), (b) and (c), but either hit the time-out limits or consume all memory resources quickly, which renders them unusable for the computations of such relationships over real world datasets. This is mainly due to the fact that the multi-transitive nature of the containment relationships creates an intractable search space, which is compensated by the dedicated specificities of our approach. From a reasoning-based perspective, it has been argued in the literature that dedicated reasoners tend to out-perform general purpose ones [8]; a fact that is supported by our experiments.

4.2 Scalability

In order to test scalability of our methods, we have created a synthetic dataset of 2.5M observations, following a similar approach as in [11]; the creation of synthetic data was based on fixing the number of dimensions and creating observations that follow a projected distribution of the data w.r.t to the real-world datasets. More specifically, we calculated the projected number of lattice nodes to reflect Figure 4(f), where the change in active lattice nodes is shown as the input size increases. Then, we populated the lattice nodes evenly.

Experiments in the datasets show that the approaches utilizing SPARQL querying and rule inferencing do not scale adequately, even for small input sizes. Figure 5(e) shows how the three proposed methods scale in respect to the in-

(a) Execution time (hours) for complementarity

(b) Execution time (hours) for full containment

(c) Execution time (hours) for partial containment

(d) Recall for three clustering algorithms w.r.t. input size

(e) log-log time and input size

(f) ratio of discovered cubes per observation count

(g) Rate of execution time with children pre-fetching vs normal for full containment

Figure 5: (a) Execution time (hours) for complementarity, (b) full containment, (c) partial containment (note that in the SPARQL based approach, partial containment is only detected and not quantified), (d) recall for three clustering algorithms w.r.t. input size, (e) log-log time and input size, (f) ratio of discovered cubes per observation count. o/m=out of memory, (g) rate of execution time with children pre-fetching vs normal for full containment.

put size. While the values for *clustering* and *cubeMasking* are based on measured values on the synthetic data, the value for the *baseline* method for 2.5m records is a projection of the quadratic analysis; it took more than 7 days to complete.

The results indicate that both *clustering* and *cubeMasking* scale better than the baseline, with the latter having a more clear advantage because of the reduced number of needed comparisons in conjunction with the fact that it is lossless. However, in extreme cases where the number of cubes is large and the distribution of observations in these cubes is sparse, the *cubeMasking* method will resemble the baseline. In these cases, the *clustering* method yields a more realistic advantage, especially when efficiency is more important than recall.

5. RELATED WORK

In this paper, we extend the work presented in [22], where we introduce preliminary notions of containment and complementarity, we outline a method of computing these notions, and define an RDF vocabulary as an extension of RDF QB for containment and complementarity between multidimensional observations across sources.

The problem of finding related observations in multidimensional spaces has been addressed within several contexts. Online Analytical Mining (OLAM) refers to the application of data mining in OLAP, and addresses OLAP classification [20], outlier detection [1], intelligent querying [28] and recommendation for OLAP exploration, which is based on either query formulation or instance similarity [2, 3]. These approaches enable discovery of latent information, exploratory analysis [13] and efficient querying [20].

In [14] the authors discuss how queries containing grouping and aggregation, which in our case is similar to observation containment, can be facilitated by materialized views. Partial containment is referred to as k-dominance in [6], where it is used to define partial skylines in multidimensional datasets.

Skyline computation in multidimensional datasets uses the notion of dominance, or observation containment, in order to assert whether a point is part of a dataset's skyline [33, 30, 19]. Skyline points are essentially top-level observations, i.e. observations that are not contained by other observations. However, these approaches are concerned with only skyline data points, rather than computation of all containment relationships. Skyline computation is, however, a direct derivative of containment computation.

Aligon et al. [2] address similarities between OLAP sessions by defining distance functions over query features. They experiment with Levenshtein, Dice's coefficient, tf-idf and Smith-Waterman, with the latter being the best for their purposes, whereas in our approach the Jaccard Coefficient addresses the binary nature of our feature space directly. Baikousi et al. [3] define distance functions for dimension hierarchies. However, they address observation similarity in general, rather than computing strict relationships as in our case. Hsu et al. [16] apply multidimensional scaling methods and hierarchical clustering in a hybrid approach in order to measure similarity between reports in the same cubes.

Business model ontologies have been deployed in the context of OLAP cubes in [29], where the authors define notions such as *merge* and *abstraction* of cubes. The *abstraction* notion is of particular interest to our work, as it resembles the

containment relationship, however the setting and motivation behind this work is representational rather than computational.

In the context of RDF, finding related cubes in multidimensional contexts is addressed in [18], where the work is focused in extending the *Drill-Across* operator to address different sources. The authors define conversion and merging correspondences between remote cubes in order to quantify the degree of their overlap and enable meaningful combinations of datasets. However, they do not address specific relationships at the instance level. The need for RDF-specific workflows is addressed in [17], where the authors argue that analytical processing of RDF cubes requires more than the capabilities offered by SPARQL engines for querying, exploration and analysis, and are best complemented with OLAP-to-SPARQL engines that use RDF aggregate views and partial materialization. This is in favour of our approach that tackles efficient materialization of batch relationships.

The more general problem of finding similarity between resources is a main component in entity resolution, record linkage and interlinking [23, 24, 32]. These approaches deal with discovering links between nodes from different datasets by using distance-based techniques. To the best of our knowledge, this is the first work that addresses the definition, representation and computation of relationships between individual multidimensional observations.

6. CONCLUSIONS AND FUTURE STEPS

In this paper, we have presented and compared three novel approaches for discovering relationships between observations of multidimensional RDF data. We have defined new relationships, namely full and partial containment, and complementarity between observations as derivatives of the hierarchical relationships between their dimension values, and as a means of comparison and correlation of their measures. We performed an experimental evaluation and comparison between them and with a SPARQL-based and a rule-based technique and we show that our methods outperform the traditional approaches in both execution time and scalability. As this work is based on batch analysis, in the future we plan to study and define efficient incremental techniques, as well as hybrid probabilistic methods that take into advantage the positive points of the *clustering* and *cubeMasking* algorithms. We will also address space efficiency and examine the behaviour of our approaches on settings with memory restrictions. Finally, we intend to examine the performance of our algorithms in distributed and parallel contexts.

ABSTRACT

During the life of a database, systematic and frequent violations of a given constraint may suggest that the represented reality is changing and thus the constraint should evolve with it. In this paper we propose a method and a tool to (i) find the functional dependencies that are violated by the current data, and (ii) support their evolution when it is necessary to update them. The method relies on the use of *confidence*, as a measure that is associated with each dependency and allows us to understand "how far" the dependency is from correctly describing the current data; and of *goodness*, as a measure of *balance* between the data satisfying the antecedent of the dependency and those satisfying its consequent. Our method compares favorably with literature that approaches the same problem in a different way, and performs effectively and efficiently as shown by our tests on both real and synthetic databases.

1. INTRODUCTION

The information related to a certain reality of interest is represented in a database by means of data, a vital resource on which decision-making processes are based. The data stored in a database must satisfy the semantic conditions expressed by the schema plus integrity constraints. Specifying and enforcing constraints grants us better data quality, maintenance, query optimization, view updating and database integration and exchange; in particular, *functional dependencies* have been widely applied to these aims and, from the 70s on, their knowledge has been used to support database design and management, reverse engineering and query optimization. The number of application scenarios they are used in has grown over time including, more recently, automated DB analysis such as knowledge discovery and data mining. A functional dependency (FD) is a constraint between two sets X and Y of attributes in a relation

R of a database: R is said to satisfy the functional dependency $X \rightarrow Y$ if each X value is associated with precisely one Y value.

Nowadays, huge amounts of data are generated daily and may come from different applications and sources where constraints are not equally enforced, thus the original datasets may be inconsistent with each other or even by themselves [1, 2]. Once a database designer or administrator is able to understand that a constraint no longer holds, he/she can decide what to do. Most systems that deal with discrepancies of this kind re-establish consistency by changing the data that violate the constraints. In our work we allow for a different interpretation. Indeed, from our point of view, changes in the data might also mean that their semantics is evolving for some reason, like for instance law or policy changes. Therefore, once the DB administrator has ascertained that this is the case, s/he will be able to re-establish consistency by appropriately modifying the violated constraints. Note that the new constraints capture a succinct representation of the new semantics of the data, thus, this kind of analysis is interesting for knowledge discovery purposes.

This paper's main goal is to propose a method to modify functional dependencies so as to adjust them to the evolutions of the modeled reality that may occur during database life. The method we propose provides a way to understand which FDs are violated and, if needed, to modify them by adding, to their antecedent, a minimal set of attributes that makes them consistent with the data.

Running example Consider the relation *Places* in Figure 1 and assume that the following FDs be defined on it:

$F_1 : [District, Region] \rightarrow [AreaCode]$

$F_2 : [Zip] \rightarrow [City, State]$

$F_3 : [PhNo, Zip] \rightarrow [Street]$

All the tuples in *Places* violate F_1 ; tuples t_1, t_2 and t_3 violate F_2 and tuples t_{10} and t_{11} violate F_3 . Thus, these three FDs are not satisfied by the data. If the DBMS is able to detect that (e.g. by means of periodic or continuous checks of FDs validity) then it can present it to the designer. Suppose the designer realizes that an FD not being satisfied by the data is not a mistake but a symptom of a real-world situation which is no more reflected by the semantics of the FDs, at this point s/he can decide to integrate some of the candidate

tid	District	Region	Municipal	AreaCode	PhNo	Street	Zip	City	State

Figure 1: Running example: relation *Places*

changes into the database. Thus, the idea of the paper is to find a way to change the constraints instead of the data and make them valid again. How can we repair an FD? First of all, without loss of generality we can assume that all FDs are decomposed so that their consequent contains a single attribute. In this way it is easy to see that modifying the consequent is a no-issue. What we can do instead is acting upon the antecedent: of course deleting attributes from it cannot repair the FD but adding attributes might. Thus, our aim is to identify the FDs violated by the data, find possible repairs and present them to the designer to be evaluated. The method can be used periodically on the data in order to keep them consistent with the constraints.

The paper is organized as follows: in Section 2 we review the state of the art, Section 3 introduces the technical notions and the considerations at the basis of our proposal, while Section 4 presents our proposal to evolve violated FDs. In Section 5 we formally compare our approach with a proposal which has the same aim as ours, but is based on the notion of entropy to measure how much an FD is far from being exact, while for the same aim we use the (simpler) notion of *confidence*. In Section 6 we explain the experimental results we have obtained on both real and synthetic datasets and finally in Section 7 we draw the conclusions of our work.

2. RELATED WORK

In the last years, research involving FDs has taken a different turn with respect to the past; today, automated data analysis has become fundamental for knowledge discovery and data mining and FDs in particular provide invaluable intensional knowledge on the relation instances. As a consequence, the concept has been used in a wide range of application scenarios, which in turn originated many extensions and variants [3], including: Conditional FDs (CFDs) [4], Approximate FDs (AFDs) [5], Approximate Conditional FDs (ACFDs) [6], Temporal FDs (TFDs) [7], Approximate Temporal FDs (ATFDs) [8], and others.

CFDs [4], have been introduced that specify FDs that do not hold on the whole relation but just on a subset of its data.

Both FDs and CFDs are exact, i.e., they hold for all the instances in the relation (in the case of FDs) or for certain subsets of it (for CFDs). These rules may easily break in the

sense that even small errors or minor changes to the relation instance may cause that the constraint no longer holds. However, as time passes by and the lifecycle of a database goes on, reality may change and so should the constraints defined on the data. It is thus appropriate to monitor data evolution as a mirror of reality in order to get useful insights about the way data are evolving in time. To this aim, allowing some exceptions in the table makes it possible to obtain a better understanding of the data. In fact, a few rows might contain errors due to various noise factors or simply be an exception to the rule, and being able to detect the presence of unexpected exceptions may inform us that something has changed in the data semantics. To deal with this scenario, AFDs have been introduced, that is, FDs that are associated with some degree of approximation. AFDs are FDs that allow some rows to contain “errors” as exceptions to the rules; the more errors they allow, the more approximate they are, that is, their “approximation degree” changes. Thus, AFDs “bend but do not break” and coherently ACFDs have been introduced as an extension of CFDs.

The problem of constraint violation has been faced in the literature in different ways. Works such as [9, 10, 11, 12, 13, 14] propose strategies to query inconsistent databases trying to re-establish consistency by changing the facts that violate the constraints. Thus, the problem of inconsistent databases is considered from a query-answering point of view, that is, the data that can produce inconsistency with respect to the integrity constraints imposed at design time are discarded. By contrast, we aim at modifying the integrity constraints so the semantics of the database will adhere as much as possible to the changing reality. Therefore, the data that violate the constraints are not considered as abnormal facts but are used to update obsolete constraints. A similar approach was developed in [15] whose authors used data mining techniques to repair tuple constraints. In this work we extend their methodology to deal with functional dependencies.

FDs have been used as means to enforce data quality through data profiling and cleaning. In [16] the authors propose an algorithm for *discovering* Denial Constraints (which include functional dependencies) without supposing that any constraint has been specified on the database at design time. In order to apply the proposal in [16] to update the constraints on a given database when they are not up to date, one has: (i) first to discover all the possible constraints from data, then (ii) relax the constraints, considered as if they

have been specified at design time on the database schema, that do not hold on the current instance. This approach is rather impractical when the FDs, though obsolete, have been originally defined by a designer, first because of efficiency reasons, and second because, as we have noticed testing the on-line algorithm of [16] the inferred constraints not always include extensions of the ones specified by the designer.

Not many works have been proposed in the literature that, in the case of inconsistency, try to change the constraints instead of the data. The authors of [17, 18] have for the first time introduced a model that considers functional dependency repair. They illustrate a method to extend, by adding one attribute, the body of a violated FD in order to obtain a new dependency that is not violated anymore. In particular, given a functional dependency $F : X \rightarrow Y$ over a relation R , each attribute of R (other than X and Y) is evaluated as a candidate using the notion of *entropy* for comparing clusterings of tuples. As a result, a ranked list of candidate attributes is given to the designer. Given an FD that is violated by the data, the strategy in [17]: i) first computes a ground truth clustering of the data, based on the attributes in the FD; ii) then, for each attribute A , not present in the FD, computes a clustering of the data based on A and finally iii) computes the relative entropy (see Section 3) between this clustering and the ground truth clustering, which means comparing all its clusters with those in the ground truth clustering. The metric used in the work, which is the information variation requires frequent clustering of tuples in order to understand how good a candidate attribute is. We propose a very simple approach based on confidence and a measure of goodness that only require to count tuples. In Section 5 we explain the details of [17] and give a theoretical comparison between this work and ours. An experimental comparison between the two approaches was unfortunately impossible due to the unavailability of the tool presented in [17].

3. BASIC NOTIONS

Let \mathcal{U} be a finite set of attribute names; we denote attributes by capital letters from the beginning of the alphabet (e.g., A, B, C, A_1 , etc.), while capital letters from the end of the alphabet (e.g., U, X, Y, Z, X_1 , etc.) are used to denote sets of attributes. Let \mathcal{D} be a finite set of domains, each containing atomic values for the attributes; the domain D_j contains the possible values for the attribute A_j . A relation schema $R(A_1, A_2, \dots, A_n)$ describes the structure of a relation whose name is R and whose set of attributes is A_1, A_2, \dots, A_n . A relation instance r of relation R , is a finite set of tuples t_1, t_2, \dots, t_m of the form $t_h = (v_1, v_2, \dots, v_n)$, where each value v_k , $1 \leq k \leq n$, is an element of D_k . $t[A_i]$ denotes the value assumed by the attribute A_i in the tuple t (i.e., v_i). Given an instance r of a relation R , we denote by $|r|$ the number of tuples in r and $|R|$ the number of attributes in R . Moreover, $\pi_X(r)$ is the projection of r on the attributes of X . The structure of a functional dependency is defined as follows:

Definition 1 (Syntax) *Given a relation schema R , a functional dependency F over R has the form $F : X \rightarrow Y$ where X and Y are sets of attributes in R .*

We use XY to denote the union of X and Y , moreover $|F| = |XY|$ is the number of attributes in the FD and, given

two FDs F_1 and F_2 , $|F_1 \cap F_2|$ is the number of attributes common to F_1 and F_2 . An instance r of a relation schema R can either satisfy an FD or not, according to Definition 2.

Definition 2 (Semantics) *Given an instance r of a relation R , r satisfies F if, for every pair of tuples t_1, t_2 in r , if $t_1[X] = t_2[X]$ then $t_1[Y] = t_2[Y]$.*

We say that an instance r is inconsistent with respect to F if it does not satisfy Definition 2.

Let us introduce a useful characterization of the notion of FD with the introduction of *confidence* and *goodness*.

Definition 3 *Let r be an instance of a relation R defined over a set of attributes S . Let X and Y be subsets of S and $F : X \rightarrow Y$ a functional dependency over R . The confidence of F w.r.t. r is:*

$$c_{F,r} = \frac{|\pi_X(r)|}{|\pi_{XY}(r)|}$$

while the goodness of F w.r.t. r is:

$$g_{F,r} = |\pi_X(r)| - |\pi_Y(r)|$$

Moreover, based on the value of the confidence of an FD, we have the following definition:

Definition 4 *Given a relation R , an instance r of R , a functional dependency F over R and its confidence $c_{F,r}$, we say that F is an exact functional dependency iff $c_{F,r} = 1$, otherwise it is an approximate functional dependency.*

All three FDs from Example 1 are approximate and have the following confidence and goodness values: $c_{F_1, Places} = 0.5$ and $g_{F_1, Places} = -2$; $c_{F_2, Places} = 0.667$ and $g_{F_2, Places} = -1$; $c_{F_3, Places} = 0.889$ and $g_{F_3, Places} = 1$. Note that the confidence of an FD reflects the average number of values of Y that are associated with each value of X in r . When the confidence is 1 it means that, for each distinct value of X , exactly one value of Y is associated with X , thus it is easy to see that exact FDs are the classical FDs of Definition 1:

The notion of functional dependency can be also formalized as a function between clusters of tuples.

Definition 5 (Clustering) *Given an instance r of a relation R and a set X of attributes of R , we call X -clustering a partition $\mathcal{C}_X = \{C_1, C_2, \dots, C_K\}$ of r into mutually disjoint subsets C_i , with $i \in \{1, \dots, K\}$, called classes (or clusters), such that each class C_i contains all the tuples of r that have the same value for the attributes in X .*

Given $F : X \rightarrow Y$, there are two clusterings naturally generated by F : \mathcal{C}_X and \mathcal{C}_Y . Intuitively, if each cluster in \mathcal{C}_X is associated with only one cluster in \mathcal{C}_Y (that is, if there is a function between classes in \mathcal{C}_X and classes in \mathcal{C}_Y) then F is satisfied, otherwise it is not. Consider as an example

$$F_1 : [District, Region] \rightarrow [AreaCode]$$

The two clusterings $\mathcal{C}_{District, Region}$ and $\mathcal{C}_{AreaCode}$ are shown in Figure 2a. As we can see, the relation between the two clusterings is not a function because there are some tuples, having the same value of *District, Region* that are associated with sets having different values of *AreaCode*. In fact, F_1 is violated by the data.

To understand whether F is satisfied or not, we consider the two clusterings \mathcal{C}_X and \mathcal{C}_{XY} . Since \mathcal{C}_{XY} is finer-grained than \mathcal{C}_X we always have: $|\mathcal{C}_{XY}| \geq |\mathcal{C}_X|$. When $|\mathcal{C}_{XY}| > |\mathcal{C}_X|$,

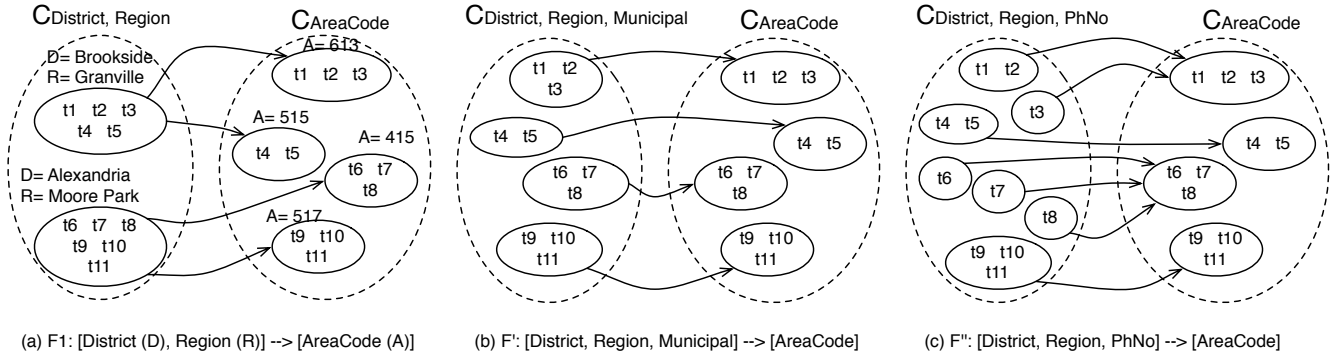

Figure 2: FDs clusterings

it means that there exists at least one class C_x in \mathcal{C}_X whose tuples form more than one class in \mathcal{C}_{XY} , thus, the relation between \mathcal{C}_X and \mathcal{C}_Y is not a function. Only when $|\mathcal{C}_{XY}| = |\mathcal{C}_X|$, we have that each class in \mathcal{C}_X forms one class in \mathcal{C}_Y and therefore F is satisfied. If there is a function between \mathcal{C}_X and \mathcal{C}_Y , such function is surjective, because each tuple in the database contains values for both X and Y ¹, thus each value of Y is necessarily associated with at least one value of X . Now, the function could be injective (and thus bijective) or not. In particular, we introduce the following definition:

Definition 6 (Proper association) *Given two clusterings \mathcal{C}_X and \mathcal{C}_Y , we say that a class C_x in \mathcal{C}_X is properly associated with a class C_y in \mathcal{C}_Y , when C_y is the unique class in \mathcal{C}_Y such that $C_x \subseteq C_y$.*

The concept of proper association is crucial for defining an FD in terms of a function between two given clusterings. Given $F : X \rightarrow Y$, when for every class C_x in \mathcal{C}_X there is a class C_y in \mathcal{C}_Y which is properly associated with C_x (i.e. C_y is the unique class that contains C_x), one usually says that the clustering \mathcal{C}_X is homogeneous with respect to \mathcal{C}_Y . Accordingly, we say that there is a *well-defined function* between the classes in \mathcal{C}_X and those in \mathcal{C}_Y . Intuitively, a well-defined function is bijective.

From our point of view, FDs that allow us to obtain a well-defined function are to be preferred to other FDs. Consider $F' : [District, Region, Municipal] \rightarrow [AreaCode]$ and $F'' : [District, Region, PhNo] \rightarrow [AreaCode]$; the clusterings \mathcal{C}_X and \mathcal{C}_Y generated by the two FDs are shown in Figure 2b and Figure 2c respectively. As we can see, in both cases there is a function between \mathcal{C}_X and \mathcal{C}_Y , however, F' allows us to obtain a well-defined function while F'' does not. Intuitively speaking, the municipality is “a better choice” than the phone number.

To explain this intuition, consider again that a non-satisfied $F : X \rightarrow Y$ generates two clusterings \mathcal{C}_X and \mathcal{C}_Y where the number of clusters in \mathcal{C}_X is smaller than the number of clusters in \mathcal{C}_Y . To obtain a function between the two clusterings, we need to “further fragment” \mathcal{C}_X so that there is the same number of clusters as in \mathcal{C}_Y , or more: in our method we do this by adding attributes to X .

Note that the number of clusters in \mathcal{C}_X gives us an idea of how “specific” is a set of attributes X , that is, if the number

¹Note that attributes involved in FDs do not contain NULL values

of clusters is 1 all the tuples in the relation are put in the same cluster, while, in the extreme case where each tuple is assigned to a distinct cluster, X is actually a candidate key.

This second case will surely happen if, while repairing F , we add to its antecedent an attribute that has the property of being UNIQUE in the relation. Adding a UNIQUE attribute allows to repair any FD because this attribute alone determines Y thus it practically makes X “useless” in the FD. Something very close to this case happens with the two dependencies F' and F'' above: F' is “better” than F'' because adding the municipality to the antecedent *allows to generate two clusterings that are associated by a function such that the specificity of the domain is as much as possible similar to the specificity of the codomain*, while, due to the high specificity of the phone number, adding it would make the antecedent too specific (also making the other attributes “almost useless”). We will see that our repairing method discourages the addition of such attributes (they are penalized through the *goodness* coefficient) and instead prefers those attributes that fragment \mathcal{C}_X just as much as it is necessary to reach the same specificity as \mathcal{C}_Y .

Notice the relationship between these concepts and the confidence and goodness of an FD F :

- F is *exact* when there is a well-defined function from \mathcal{C}_X to \mathcal{C}_Y , that is, the *confidence coefficient* of an FD somehow measures the “degree of being a function” ($c_{F,r} \leq 1$).
- When this pleasant fact happens ($c_{F,r} = 1$), then the *goodness coefficient* measures how far our function is from being injective. In fact it is injective when $g_{F,r} = 0$. In any case, when $c_{F,r}$ is different from 1, the *goodness coefficient* measures the distance of our approximate FD from having the domain with the same cardinality of the co-domain.

Therefore the case $\{c_{F,r} = 1, g_{F,r} = 0\}$ is such that to each class in \mathcal{C}_X is associated one and only one class in \mathcal{C}_Y : the corresponding FD allows to obtain a bijective function between the two clusterings and so it is the best function which cannot be further improved. In fact, from a well-known result on functions², since the correspondence F is surjective and $|\pi_X(r)| = |\pi_Y(r)|$, it is therefore bijective. Finally we

²Let $f : X \rightarrow Y$ be a function. If $|X| = |Y|$, then f is injective if and only if f is surjective.

notice that the *goodness coefficient* can be positive or negative. It is positive when the domain cardinality is higher than the co-domain one and negative instead when the cardinality of the domain is smaller.

As a final remark, notice that, if the DB schema is in a higher normal form, the only non-trivial FDs are those determining candidate keys. However, we believe this to be a strong assumption, especially nowadays, since NoSQL, semi-structured and other types of poorly organized data are widely used. Thus, we do not rely on the assumption that a database is in a higher normal form and obtaining some insight about the data becomes very important in such a scenario.

4. EVOLVING FUNCTIONAL DEPENDENCIES

The goal of our method is to: (i) understand which FDs are violated and (ii) repair these FDs by adding attributes to the antecedent of the dependency.

Objective *Given an FD $F : X \rightarrow Y$, not satisfied by the data, our aim is to find a minimal set of attributes U such that the new FD $F^U : XU \rightarrow Y$ is satisfied by the data.*

Given a relation schema R , an instance r of R , and all the FDs defined on it, for each FD, $F : X \rightarrow Y$, we compute its confidence. If the result is lower than 1 then the FD is not satisfied and, to repair it, we look for a set of attributes U in $R \setminus XY$ such that, if added to the antecedent of F , generate a new dependency $F^U : XU \rightarrow Y$ whose confidence is 1.

4.1 FD ordering

If an instance r of a relation R violates more than one constraint we need to decide the order in which they should be repaired. To do this, similarly to [17], for each FD F we compute a rank that is the average of two indicators:

1. $ic_{F,r}$: the “degree of inconsistency” of F with respect to the relation r : $ic_{F,r} = 1 - c_{F,r}$
2. cf_F : the “conflict score” of F with respect to the other FDs defined on R , which is independent of any specific instance and depends on the number of attributes that F has in common with these FDs:

$$cf_F = \frac{\sum_{F' \in \mathcal{F}} \frac{|F \cap F'|}{\max(|F|, |F'|)}}{|\mathcal{F}|}$$

where \mathcal{F} is the set of FDs defined on R .

The final rank is the average of these two indicators:

$$O_F = \frac{ic_{F,r} + cf_F}{2}$$

Given a set \mathcal{F} of FDs, we sort \mathcal{F} according to the rank O_F of each $F \in \mathcal{F}$ and then follow this order to repair the FDs. Consider the relation in Figure 1 and the three FDs F_1 , F_2 and F_3 in Example 1. The constraints should be examined in the following order: F_1 (0.25), F_2 (0.167), F_3 (0.056).

4.2 Candidate-repair ordering for an FD

Given an instance r of a relation R , an FD $F : X \rightarrow Y$ and an attribute A which is a candidate to extend the antecedent

of FD, we first compute the confidence of the candidate FD $F^A : XA \rightarrow Y$ as:

$$c_{F^A,r} = \frac{|\pi_{XA}(r)|}{|\pi_{XAY}(r)|}$$

and then provide an ordered list of candidate attributes sorted in descending order of $c_{F^A,r}$. However, this ranking does not allow us to distinguish which attribute is better when the FDs they produce have the same confidence. Consider $F_1 : [District, Region] \rightarrow [AreaCode]$ defined on table *Places*. Intuitively, if we add the attribute *Municipal* to the antecedent of F_1 we obtain an exact FD and, similarly, if we instead add the attribute *PhNo* we also obtain an exact FD. Now, is it more reasonable to add the municipality or the phone number as attribute that is part of a functional dependency? Which one is better and why?

To provide a better ranking, following the intuition explained in Section 3 we use the goodness of F^A , which depends on the number of distinct values A assumes, as shown in Definition 3:

$$g_{F^A,r} = |\pi_{XA}(r)| - |\pi_Y(r)|$$

Once we have computed both the confidence and the goodness of each attribute in $R \setminus XY$, we produce, for each violated FD, a ranked list of candidate attributes, sorted first according to $c_{F^A,r}$ and then, as secondary sorting key, according to $g_{F^A,r}$. Consider $F_1 : X \rightarrow Y$ with $X = [District, Region]$ and $Y = [AreaCode]$. The confidence and goodness of F_1 are:

$$c_{F_1, Places} = \frac{|\pi_{District, Region}(Places)|}{|\pi_{District, Region, AreaCode}(Places)|} = \frac{2}{4} = 0.5$$

$$g_{F_1, Places} = |\pi_{District, Region}(Places)| - |\pi_{AreaCode}(Places)| = 2 - 4 = -2$$

F_1 is not satisfied by the tuples in *Places*, thus, for each candidate attribute A in relation *Places* we compute the two parameters $c_{F_1^A, Places}$ and $g_{F_1^A, Places}$ (Table 1 shows the results). The two candidate attributes $Z_1 = [Municipal]$

A	$c_{F_1^A, Places}$	$g_{F_1^A, Places}$
Municipal	4/4 = 1	0
PhNo	7/7 = 1	3
Street	7/8 = 0.875	3
Zip	4/5 = 0.8	0
City	4/5 = 0.8	0
State	3/5 = 0.6	-1

Table 1: Evolving $F_1 : [District, Region] \rightarrow [AreaCode]$

and $Z_2 = [PhNo]$ allow us to obtain new *exact* FDs, while every other attribute does not. Moreover, attribute Z_1 has a better rank because it allows to discriminate the distinct values of *District*, *Region*, *AreaCode* in a homogeneous way.

4.3 When more than one attribute is needed

Until now we have assumed that we repair an FD by adding only one attribute to its antecedent. Of course, it might happen that adding only one attribute is not enough to obtain an exact new FD. In this case, we can either stop or try to find a “more specific” FD by adding more attributes to

its antecedent. We handle this scenario as an iterative process where, at each step of iteration, the method presented so far is applied. Thus, at each step we have to choose the next attribute to be added to the antecedent and we do so by adding the attribute that produces the candidate FD with the highest rank. Consider $F_4 : X \rightarrow Y$ with $X = [District]$ and $Y = [PhNo]$, whose confidence and goodness are:

$$c_{F_4, Places} = \frac{|\pi_{District}(Places)|}{|\pi_{District, PhNo}(Places)|} = \frac{2}{7} = 0.29$$

$$g_{F_4, Places} = |\pi_{District}(Places)| - |\pi_{PhNo}(Places)| = 2 - 6 = -4$$

Thus, F_4 is not satisfied, and Table 2 shows the ranking of the attributes which are candidates to extend it.

A	$c_{F_4^A, Places}$	$g_{F_4^A, Places}$
Street	0.875	1
Municipal	0.571	-2
AreaCode	0.571	-2
City	0.571	-2
Zip	0.5	-2
State	0.429	-3
Region	0.286	-4

Table 2: Evolving $F_4 : [District] \rightarrow [PhNo]$

As we can see, there is no attribute that allows us to obtain an exact new FD thus we proceed by adding the attribute that generates the candidate FD with the highest rank. We obtain a new FD which is still not exact and then apply our method again to look for attributes that can be added to its antecedent. Therefore, we add attribute *Street* to the antecedent of F_4 and obtain $F_4^{Street} : [District, Street] \rightarrow [PhNo]$. Table 3 shows the ranking of the attributes which are the candidates to extend F_4^{Street} .

B	$c_{F_4^{Street, B}, Places}$	$g_{F_4^{Street, B}, Places}$
Municipal	1	4
AreaCode	1	4
Zip	0.889	4
City	0.875	4
State	0.875	3

Table 3: Evolving $F_4^{Street} : [District, Street] \rightarrow [PhNo]$

We have found two attributes, *Municipal* and *AreaCode*, that allow to extend F_4 and obtain an exact new FD. Therefore, the two pairs *Street, Municipal* and *Street, AreaCode* allow to extend the antecedent of F_4 and obtain an exact new FD. They score the same value also for the goodness thus they are actually equivalent w.r.t. our aim. In such a case, it is for the designer to choose which one is more significant w.r.t. the application scenario.

4.4 Algorithm

Our approach is formalized by Algorithm 1 which receives as input a relation R (both instance and schema) and the set \mathcal{F} of FDs defined over R . First of all, the function **OrderFDs** (line 2) orders all FDs according to the rank introduced in Section 4.1. Then, for each functional dependency

F , the algorithm computes its confidence $c_{F,r}$ (line 4) in order to understand whether the FD is satisfied or not. If it is not satisfied, it calls the **ExtendByOne** function that computes the confidence and goodness (w.r.t. F) of all attributes in R other than those that are already in F (lines 3 and 4 in Algorithm 2) and returns the set of all candidates sorted according to their rank. Finally, if the considered attribute allows to obtain an exact new FD, it is added to the set of exact new FDs (line 9 in Algorithm 1).

Algorithm 1 FindFDRepairs (pseudocode).

Input: R the schema of a relation

r the instances of R

\mathcal{F} the functional dependencies defined on R

Output: *Exact* the set of exact FDs obtained

```

1: Exact =  $\langle \rangle$ ; Cand =  $\langle \rangle$ 
2: FDs = OrderFDs( $\mathcal{F}$ )
3: for all  $F : X \rightarrow Y \in \mathcal{F}$  do
4:    $c_{F,r} = \frac{|\pi_X(r)|}{|\pi_{XY}(r)|}$ 
5:   if  $c_{F,r} < 1$  then
6:     Cand = ExtendByOne( $F, R, r$ )
7:     for all  $\langle F', c_{F',r}, g_{F',r} \rangle \in \textit{Cand}$  do
8:       if  $c_{F',r} = 1$  then
9:         Exact = addInOrder(Exact,  $\langle F', c_{F',r}, g_{F',r} \rangle$ )
10:      end if
11:    end for
12:  end if
13: end for
14: return Exact
```

Notice that the computation of confidence and goodness can be implemented using SQL queries. In fact, the values $|\pi_X(r)|$, $|\pi_{XY}(r)|$, $|\pi_{XA}(r)|$, $|\pi_{XAY}(r)|$, $|\pi_{XY}(r)|$, $|\pi_A(r)|$ used in the algorithm are computed by counting the number of distinct tuples over the set of attributes involved in the antecedent and consequent of the FD. For example, the confidence of F_1 , is the ratio between the results of:

Q_1 : `select count(distinct District, Region)`
`from Places`

Q_2 : `select count(distinct District, Region, AreaCode)`
`from Places`

The computation of these queries heavily depends on the query plan implemented by the DBMS and on the presence of supporting data structure such as indices. What we can say is that, considering the worst case scenario where no optimization techniques are implemented, we have a $O(n \log n)$ complexity because counting the distinct values corresponds to a sorting ($O(n \log n)$) followed by counting ($O(n)$). Moreover, looking for a single attribute at a time to extend the antecedent of an FD is linear with respect to the number of attributes in the relation.

However, when looking for repairs that contain more than one attribute, things get more complicated because the number of candidate repairs grows exponentially with respect to the number of attributes. To limit this problem we use a greedy algorithm that chooses the FD candidates according first to the number of attributes in their antecedent and then to their rank. To this aim, we modify Algorithm 1 by introducing a queue that contains candidate repairs sorted by increasing cardinality of the antecedent and decreasing

Algorithm 2 ExtendByOne (F, R, r) pseudocode.

```
1:  $Cand = \langle \rangle$ 
2: for all  $A \in R \setminus XY$  do
3:    $c_{FA,r} = \frac{|\pi_{XA}(r)|}{|\pi_{XAY}(r)|}$ 
4:    $g_{FA,r} = |\pi_{XA}(r)| - |\pi_Y(r)|$ 
5:   if  $c_{FA,r} = 1$  then
6:      $Cand = \text{addInOrder}(Cand, \langle F^A, c_{FA,r}, g_{FA,r} \rangle)$ 
7:   end if
8: end for
9: return  $Cand$ 
```

rank: given an FD F that needs to be evolved, Algorithm 3 first generates all the candidates obtained by adding one attribute to the antecedent of F (line 1) and inserts them into a queue ordered by decreasing rank (line 2). Then, one at the time, it removes the first candidate in the queue (line 4); if its confidence is 1, it adds it to the set of candidates that allow to find an exact FD (line 6), otherwise it generates all the candidates obtained by adding one attribute to the antecedent of the FD (line 8) and inserts them into the queue, again sorted first by increasing cardinality of their antecedent and then by decreasing rank (line 9). The process is repeated while there are still candidates left in the queue and, at the end of the process, the algorithm returns the set of all candidates that allow to obtain an exact FD (line 12). Notice two things: (i) the stop condition of the algorithm can be easily changed to end when the first repair is found (in this way the algorithm does not need to explore the whole search space); (ii) since the candidates in the queue are ordered first according to the number of attributes in their antecedent (and then according to their rank), the first repair found is also a minimal one, that is, it contains the minimum number of attributes that need to be added to the antecedent of the considered FD to repair it.

Algorithm 3 Extend (F, R, r) (pseudocode).

```
1:  $Cand = \text{ExtendByOne}(F, R, r)$ 
2:  $\text{addInOrder}(\text{Queue}_F, Cand)$ 
3: while  $\text{Queue}_F$  not empty do
4:    $\langle F', c_{F',r}, g_{F',r} \rangle = \text{removeFirst}(\text{Queue}_F)$ 
5:   if  $c_{F',r} = 1$  then
6:      $\text{addInOrder}(\text{Exact}, \langle F', c_{F',r}, g_{F',r} \rangle)$ 
7:   else
8:      $Cand = \text{ExtendByOne}(F', R, r)$ 
9:      $\text{addInOrder}(\text{Queue}_F, Cand)$ 
10:  end if
11: end while
12: return  $\text{Exact}$ 
```

The complexity of managing the queue corresponds to the complexity of a sorting algorithm. Of course, the number of candidates inserted into the queue is exponential with respect to the number of attributes in the relation. In order to find all candidates that allow to obtain an exact FD we need to explore the whole search space. However, this does not happen if we decide to stop when we find the first candidate instead. In the latter case, given the ordering we use to explore the search space, we can ensure that we reach our objective, as stated at the beginning of Section 4, that is, that we are able to find a minimal repair for a given FD.

Notice that a minimal repair might not always be the

best choice. Suppose we are trying to repair a given FD $F : X \rightarrow Y$ and suppose there are two ways to do it: i) we can add attribute A which has the property of being UNIQUE and ii) we can add the two attributes B and C , neither of whom is UNIQUE. Of course, since we privilege shorter repairs, the algorithm will privilege the first repair which unfortunately goes against what we have discussed in Section 3. To address this drawback we are currently investigating the use of a user-specified maximum goodness threshold. The idea is to use it to privilege those repairs whose goodness is lower than the threshold. In particular, we are currently considering combining such a threshold with our confidence and goodness measures in order to provide an objective function that guides our repair strategy.

5. THEORETICAL COMPARISON WITH THE ENTROPY-BASED APPROACH

The technique presented in [17] finds attributes that are good candidates to extend the antecedent of an FD, based on its variation of information, which in its turn is based on the entropy measure. In this section we dub this Entropy-Based method EB, and compare it with ours (CB) which is based mainly on the Confidence measure.

Even though the aim of the EB method is the same as ours, there are some differences between them: the first difference is that CB easily supports the evolution of an FD by adding more than one attribute in its antecedent; second, and more important, to understand if an attribute is a good candidate to extend the FD, we only compute its confidence, while with EB more complex computations are needed. To discuss this, we need to introduce formally the notion of *Entropy*.

Given two clusterings \mathcal{C} and \mathcal{C}' , we can compute the *Variation of Information* (VI) [19] between them as the sum of the two conditional entropies:

$$VI(\mathcal{C}, \mathcal{C}') = H(\mathcal{C}|\mathcal{C}') + H(\mathcal{C}'|\mathcal{C})$$

where the conditional entropy of \mathcal{C} given \mathcal{C}' is defined as:

$$H(\mathcal{C}|\mathcal{C}') = - \sum_{k=1}^K \sum_{k'=1}^{K'} P(k, k') \log P(k|k')$$

where: $P(k, k') = \frac{|C_k \cap C'_{k'}|}{n}$ is the joint probability distribution associated to the pair $(\mathcal{C}, \mathcal{C}')$,

$$P(k|k') = \frac{P(k, k')}{P(k')} = \frac{|C_k \cap C'_{k'}|}{|C'_{k'}|}$$

is the conditional probability distribution associated to \mathcal{C} given \mathcal{C}' , and $P(k') = \frac{|C'_{k'}|}{n}$ the marginal probability distribution associated to \mathcal{C}' . Note that $VI(\mathcal{C}, \mathcal{C}')$ is symmetric with respect to the two clusterings.

Given $F : X \rightarrow Y$, the EB method creates a ground truth clustering \mathcal{C}_{XY} and then looks for an attribute A that, when added to the antecedent of F , allows to obtain a clustering \mathcal{C}_{XA} that is either homogeneous or, preferably, homogeneous and *complete* w.r.t. \mathcal{C}_{XY} (i.e., with VI equal to zero).

Note that, with EB, for each FD, the algorithm computes a ground truth clustering that is obtained by scanning all tuples and grouping them according to the attributes in the FD; then, for each attribute A in the relation, the algorithm computes the clustering \mathcal{C}_A of the relation in the same manner; and finally the two clusterings must be compared by

computing the intersections of all pairs of clusters in order to determine the variance of information. This last action requires, for each cluster in the ground truth clustering, to scan all clusters in \mathcal{C}_A . Thus, the EB method requires to store the tuples in order to be able to perform the intersections between clusters while with the CB technique we do not keep trace of all tuples in the groups but only of their amount.

We now show that the *confidence* and *goodness* parameters introduced in Section 3 can be successfully used instead of the conditional entropies and that these two simple parameters give rise to a measure which is equivalent to the VI measure.

Given $F : X \rightarrow Y$, the EB method chooses \mathcal{C}_{XY} as the ground truth clustering and, for each attribute A , considers the clustering \mathcal{C}_A in order to understand how well it matches \mathcal{C}_{XY} . This is done by taking advantage of the two conditional entropies involved in the definition of VI, but *not symmetrically*. In fact, a modified version of the VI is introduced that considers first the conditional entropy of \mathcal{C}_{XY} given \mathcal{C}_{XA} , i.e. $H(\mathcal{C}_{XY}|\mathcal{C}_{XA})$, and then the conditional entropy of \mathcal{C}_A given \mathcal{C}_{XY} , i.e. $H(\mathcal{C}_A|\mathcal{C}_{XY})$. Then, the EB approach selects the attribute A that has the lowest value of $H(\mathcal{C}_{XY}|\mathcal{C}_{XA})$ and, in the case of a tie, the attribute A with the lowest value of $H(\mathcal{C}_A|\mathcal{C}_{XY})$.

The first conditional entropy $H(\mathcal{C}_{XY}|\mathcal{C}_{XA})$ measures the *non homogeneity* property of \mathcal{C}_{XA} with respect to \mathcal{C}_{XY} . In fact, it is easy to see that when a class $C_{xa} \in \mathcal{C}_{XA}$ is such that $C_{xa} \subseteq C_{xy}$ for some $C_{xy} \in \mathcal{C}_{XY}$, then

$$\log P(C_{xy}|C_{xa}) = \log \frac{P(C_{xy} \cap C_{xa})}{P(C_{xa})} = \log \frac{P(C_{xa})}{P(C_{xa})} = 0$$

Thus, when \mathcal{C}_{XA} is *homogeneous* with respect to \mathcal{C}_{XY} , the relative conditional entropy $H(\mathcal{C}_{XY}|\mathcal{C}_{XA})$ is zero. Similarly, the second conditional entropy $H(\mathcal{C}_A|\mathcal{C}_{XY})$ is zero when every class $C_{xy} \in \mathcal{C}_{XY}$ is such that $C_{xy} \subseteq C_a$ for some $C_a \in \mathcal{C}_A$. When this happens, the completeness property for \mathcal{C}_A versus \mathcal{C}_{XY} is verified.

The best attribute found by the EB technique is both *homogeneous* and *complete* implying that the VI is zero.

In the following we propose a slight variation of the EB approach of [17], based on the original definition on VI as in [19], i.e.

$$VI(\mathcal{C}_{XY}, \mathcal{C}_{XA}) = H(\mathcal{C}_{XY}|\mathcal{C}_{XA}) + H(\mathcal{C}_A|\mathcal{C}_{XY})$$

This allows us to make the comparison clearer, while not affecting the results. Note that, given $F : X \rightarrow Y$, VI can be seen as a measure, denoted by $\varepsilon_{VI} := VI$, on all FDs $F^A : XA \rightarrow Y$, where A is, as introduced in Section 4.2, a candidate attribute to repair F . This measure is equal to zero when there is homogeneity and completeness between the two clusterings \mathcal{C}_{XA} and \mathcal{C}_{XY} . Let us also introduce the measure ε_{CB} , based on our *confidence* and *goodness* coefficients of Definition 3:

$$\varepsilon_{CB} := i_{FA} + \hat{g}_{FA}$$

where $i_{FA} := 1 - c_{FA}$ is the “degree of inconsistency” introduced in Section 4.1 and $\hat{g}_{FA} := |g_{FA}|$ is the absolute value of the goodness coefficient. This measure is equal to zero when F^A allows to generate a bijective function between the classes of \mathcal{C}_{XA} and those of \mathcal{C}_Y . We can state that the two measures are equivalent, i.e. they have the same null

sets (the sets where they assume the null value) and, consequently, the same support sets (the sets where the measures assume a strictly positive value):

Theorem 1 *Let R be a relation schema and $F^Z : XZ \rightarrow Y$ a functional dependency defined on R as above. Then the measures ε_{CB} and ε_{VI} are equivalent.*

Proof 1 *First we observe that the CB best case $\{c_{FZ} = 1, g_{FZ} = 0\}$ corresponds to $\{\varepsilon_{CB} = 0\}$ and the EB best case $\{VI = 0\}$ corresponds to $\{\varepsilon_{VI} = 0\}$.*

Let us recall that given two measures P and Q , the measure P is absolutely continuous w.r.t. the measure Q (or P is dominated by Q) if for all A such that $Q(A) = 0$ one has that $P(A) = 0$, i.e. when the null sets of Q are also null sets of P . Moreover in this case by Radon-Nikodym theorem (see [20]) there exists a (positive) density f such that in differential form one has that $dP = fdQ$. If in addition Q is also absolutely continuous w.r.t. P , then the two measures are called equivalent. In particular in this case one can show that $dQ = f^{-1}dP$ ([20]).

We prove that ε_{VI} is absolutely continuous w.r.t. ε_{CB} . We put $B = F^Z : XZ \rightarrow Y$ and suppose that $\varepsilon_{CB}(B) = 0$. Then $\{c_{FZ} = 1\}$ and $\{g_{FZ} = 0\}$. When the confidence is equal to one we also have the homogeneity property of \mathcal{C}_{XZ} versus \mathcal{C}_{XY} . In fact when $\{c_{FZ} = 1\}$ there is a proper association for every $C_{xz} \in \mathcal{C}_{XZ}$, that is:

$$\forall C_{xz} \in \mathcal{C}_{XZ} \quad \exists! \quad C_y \in \mathcal{C}_Y \quad \text{s.t.} \quad C_{xz} \subseteq C_y$$

Thus, \mathcal{C}_{XZ} is homogeneous with respect to \mathcal{C}_Y and it follows that \mathcal{C}_{XZ} is homogeneous also with respect to \mathcal{C}_{XY} , i.e.:

$$\forall C_{xz} \in \mathcal{C}_{XZ} \quad \exists! \quad C_{xy} \in \mathcal{C}_{XY} \quad \text{s.t.} \quad C_{xz} \subseteq C_{xy}$$

In fact if there exists a C_{xz} whose tuples are contained in more than one class C_{xy} , it would be $|\mathcal{C}_{XZ}| < |\mathcal{C}_{XY}| \leq |\mathcal{C}_{XZY}|$. But this cannot happen, since

$$\{c_{FZ} = 1\} \Leftrightarrow |\mathcal{C}_{XZ}| = |\mathcal{C}_{XZY}|$$

Therefore, also the confidence coefficient of the CB method is a measure of the homogeneity property of \mathcal{C}_{XZ} versus \mathcal{C}_{XY} : there is homogeneity when the confidence coefficient is one.

Moreover, when in addition also the goodness coefficient is zero, the clustering \mathcal{C}_{XZ} has also the completeness property versus \mathcal{C}_{XY} , in the sense that $H(\mathcal{C}_{XZ}|\mathcal{C}_{XY}) = 0$. In fact, we recall that a clustering has the cited completeness property when

$$\forall C_{xy} \in \mathcal{C}_{XY} \quad \exists! \quad C_{xz} \in \mathcal{C}_{XZ} \quad \text{s.t.} \quad C_{xy} \subseteq C_{xz}$$

If there exists a class C_{xy} whose tuples are in part contained in some C_{xz} and in part in some other \hat{C}_{xz} , then it would be $|\mathcal{C}_Y| \leq |\mathcal{C}_{XY}| < |\mathcal{C}_{XZ}|$. But this cannot happen, since

$$\{g_{FZ,r} = 0\} \Leftrightarrow |\mathcal{C}_{XZ}| = |\mathcal{C}_Y|$$

Since the homogeneity plus completeness properties between the two clusterings implies $\varepsilon_{VI} = 0$ we have proved that the measure ε_{VI} is dominated by the measure ε_{CB} .

We show that ε_{CB} is dominated by ε_{VI} . Let us suppose that $\varepsilon_{VI}(B) = 0$. Then $VI = 0$, which implies that the homogeneity and the completeness properties hold. As a consequence the two clusterings are exactly equal, i.e. every single class in correspondence contains the same subset of tuples. In particular this means that: a) $|\mathcal{C}_{XY}| = |\mathcal{C}_{XZ}|$

b) $\forall y \quad \exists! \quad (x, z)$ and therefore $|\mathcal{C}_{XZ}| = |\mathcal{C}_Y|$

c) $\forall(x, z) \exists! y = z$ and therefore $|\mathcal{C}_{XZY}| = |\mathcal{C}_{XZ}|$
and this implies $ic_{FZ} = 0$ and $g_{FZ} = 0$, i.e. $\varepsilon_{CB}(B) = 0$.

Finally the two measures are equivalent: they have the same null sets and, consequently, the same support sets (that is the sets where the measures assume strictly positive values). Moreover by Radon-Nikodym theorem there exists a positive density f , such that

$$d\varepsilon_{CB}(B) = f(B)d\varepsilon_{VI}(B), \quad d\varepsilon_{VI}(B) = f^{-1}(B)d\varepsilon_{CB}(B).$$

The proof of Theorem 1 shows that the two measures have the same support sets (i.e. the sets where a measure assumes strictly positive values).

We remark that the measures ε_{VI} and ε_{CB} can be considered as acting on a general $F : X \rightarrow Y$, with X and Y sets of attributes in R , and in this case they assume respectively the form

$$\varepsilon_{VI}(F) = H(\mathcal{C}_{XY}|\mathcal{C}_Y) + H(\mathcal{C}_Y|\mathcal{C}_{XY})$$

and

$$\varepsilon_{CB}(F) := ic_F + \hat{g}_F.$$

Moreover it can be proved, in the same way as for Theorem 1, that they are equivalent measures.

Usually the equivalence relation between measures is rather weak: they have the same support sets but the values they assume can be very different. Since in our case the number of possible FDs is finite and our measures are finite too, the absolutely continuity property is a sort of continuity property between the two measures; more precisely, one can prove that, in our finite case, the mutual absolutely continuity property of ε_{CB} and ε_{VI} is equivalent to the following $\epsilon - \delta$ property:

$\forall \epsilon \exists \delta$ s.t. $\varepsilon_{CB}(A) < \epsilon$ for each A with $\varepsilon_{VI}(A) < \delta$ (and the same relation holds with ε_{CB} and ε_{VI} interchanged).

As a consequence, our measures are equivalent and assume comparable values in their support sets. Moreover both EB and CB are based on algorithms which are looking for exactly the sets where the two measures assume the value zero.

We want to stress the fact that the CB method is indeed simpler than the EB approach both from the conceptual and computational point of view. First, because CB uses the classical framework of set functions with well-known elementary mathematical concepts. Moreover, with CB we have to perform only a few cardinality computations of the notable clusterings associated to a given FD in order to achieve our ranked list of attributes, i.e. with no need to enter in the detailed structure of the involved clusterings.

We have compared our CB approach only with the EB method in [17]. We think that this comparison is sufficient for the following reasons. In [21] it has been shown that from an axiomatic point of view the best *approximation measure* for FDs is the *information dependency measure*. One can easily prove that the measure introduced in [21] for an arbitrary FD $F : X \rightarrow Y$ is a normalized version of the first conditional entropy entering in the VI, that is $H(\mathcal{C}_{XY}|\mathcal{C}_X)$. We observe that also what we call “degree of inconsistency” $ic_F = 1 - c_F$ can be seen as an *approximation measure* of how far the given FD is from generating an exact function and that from the proof of Theorem 1 one can deduce that our measure ic_F is equivalent to the *approximation measure* given by $H(\mathcal{C}_{XY}|\mathcal{C}_X)$. Since in [21] there is also an accurate and complete review of the *approximation measures* in the

literature, we finally conclude that the comparison of our CB method with the EB approach proposed in [17] is sufficient. It is now quite clear that the CB method grants results that are fully comparable with those obtained by means of the EB method, with the important difference that the basic concepts and the required computations are much simpler.

6. EXPERIMENTAL RESULTS

We implemented our method in a Java prototype tool. Initially, users connect to a MySQL database and visualize its relations and all FDs defined on each relation; then, they are allowed to add other FDs to the ones that are already defined, and finally they can start the process of FD validation.

We tested the tool on both real and synthetic databases and studied the time needed to find FD repairs. Our study was conducted varying both the FDs and the number of attributes and tuples in the relations.

All the experiments were run on a Core i5 2.6 GHz PC with 4 GB of memory and Windows 8 x64 operating system.

6.1 Synthetic databases

We used DBGEN to independently generate three synthetic databases of different sizes: Table 4 shows the features of the generated relations in terms of numbers of attributes and tuples. For each instance of the three databases, we defined one FD on each relation and run our algorithm to understand how execution time varies depending on the dimension of the dataset. Notice that, as shown in Table 5, all FDs have one attribute in the antecedent and one in the body and by processing time we mean the time it took for the algorithm to find all possible repairs for the given FD.

Table	arity	100MB	250MB	1GB

Table 4: TPC-H Databases Overview

Figure 3 shows, for the 1GB synthetic database, how the processing time varies depending on the number of attributes (Figure 3a), number of tuples (Figure 3b) and overall dimension of the table (Figure 3c).

We report only the plots related to the 1GB database because of space limitations. However, we noticed that the time needed to repair the FDs is higher for bigger datasets, but the trend is the same. In fact, the trends for the 100MB and 250MB databases are very similar to the one for the 1GB database, although on a smaller scale. This happens because the structure of the three datasets is the same, thus what changes is only the number of tuples. Synthetic datasets tend to behave in a somehow “uniform” way, thus we performed a study on real datasets, with the aim of understanding in what way the number of attributes and the number

Table	FD	100MB	250MB	1GB

of tuples in a relation influence the algorithm.

6.2 Real-life databases

We conducted our experiments using the relations listed in Table 6, which also summarizes, for each of them, the number of attributes and tuples. On each relation we defined an FD containing one attribute in the antecedent and one in the consequent and then run our algorithm to find one possible repair (that is, the algorithm stops when it finds the first repair). Table 6 shows the results in terms of the time needed to execute the task.

Table	arity	card.	FD process time
Places	9	10	257ms
Country ³	15	239	32ms
Rental ⁴	7	16044	588ms
Image ⁵	14	124768	2m 52s
PageLinks ⁶	3	842159	4s 678ms
Veterans ⁷	481	95412	29m 45s

Table 6: Real Databases Overview and processing times

We can see that relations with a higher number of attributes take longer time to be processed while the same does not hold in general for relations with high amounts of tuples. In fact, as we will see in the next Section, the time grows exponentially with the number of attributes while tuples do not influence it so much.

³<http://dev.mysql.com/doc/index-other.html>

⁴<http://dev.mysql.com/doc/index-other.html>

⁵<http://dumps.wikimedia.org/backup-index.html>

⁶<http://dumps.wikimedia.org/backup-index.html>

⁷<http://kdd.ics.uci.edu/databases/kddcup98/kddcup98.html>

There are many factors that influence execution time: these mainly concern the content of the tables (e.g. number of null values, number of candidates at one level that improve confidence, etc . . .), whose impact on computation time needs to be studied in details. For example, in the results shown in Table 6 we have that even though Places is a smaller relation than Country (both in terms of attributes and tuples) it took longer to compute the results. This happens because for the first relation, longer repairs were needed, in fact, for table Places, the algorithm added 2 attributes to repair the given FD while for relation Country it added only 1 attribute. Moreover, we can see that even though table PageLinks is the biggest one in terms of tuples, it took less time to repair it than the Image table. This happens because the PageLinks relation has only three attributes, and since the FD defined on it has already two attributes (one in the antecedent and one in the consequent) the algorithm had to consider only the third one in the table. On the other hand, in the Image table, the algorithm had to add 2 attributes to the antecedent of the FD to repair it.

Nr. of tuples	Nr. of attributes		
	10	20	30
10K	26s	4m16s	17m34s
20K	38s	7m56s	35m1s
30K	57s	11m47s	51m48s
40K	2m13s	15m29s	1h28m12s
50K	2m44s	19m34s	1h48s
60K	3m17s	22m51s	1h56m3s
70K	5m13s	36m36s	2h23m8s

Table 7: Processing times for the Veterans relation – find all repairs

6.2.1 Case study

To better understand how the number of attributes and the number of tuples in a relation influence our algorithm, we performed a case study using the Veterans relation (see Table 6) which has 481 attributes (323 of which do not have null values) and 95412 tuples containing only non-null values. Notice that, since the attributes occurring in an FD are not allowed to contain NULL values, when generating candidate repairs, we only consider the addition of those attributes that do not contain NULLs. We created several instances of this relation, each containing a different number of attributes and tuples. We defined an FD containing one attribute in the antecedent and one in the consequent and then run our algorithm to find: (i) all possible repairs (Table 7 shows the results) and (ii) the first repair (results in Table 8). From these results we can confirm the evidence of the synthetic dataset study, namely, that execution time grows much quicker with the number of attributes in the relation than with the number of tuples. Computation time grows exponentially with the number of attributes while an increase in the number of tuples implies longer query processing times, but does not affect the algorithm processing time so much. Moreover, we can see that processing times are much smaller if the algorithm stops when it finds the first repair instead of exploring the whole search space. However, it might happen that the two times are very similar (e.g. in the 70K tuples DB with 10 attributes) when the algorithm is not able to find a repair for the given FD.

Nr. of tuples	Nr. of attributes		
	10	20	30
10K	8s76ms	53s96ms	2m23s
20K	18s22ms	1m30s	4m10s
30K	27s64ms	2m15s	6m12s
40K	1m25s	3m4s	8m18s
50K	1m47s	3m46s	10m38s
60K	2m10s	4m44s	12m51s
70K	5m23s	5m57s	16m10s

Table 8: Processing times for the Veterans relation – find the first repair

During the experiments we noticed that there are other parameters, generally application-dependent, that influence our method. Just to name a few: (i) the number of distinct values of an attribute: the more distinct values there are, the more time is needed to compute the queries; (ii) the initial confidence of an FD: as can be expected, the smaller the initial confidence, the greater the probability that a longer repair is needed, that is, the more attributes should be added in the antecedent, thus requiring more time; (iii) the average length of the repairs: if an FD needs repairs that add many attributes to the antecedent it will require more computation time. These parameters are related to each other, depend on the domain of application and are very difficult to control and predict.

6.3 Quality of results

We claim that our criterion for choosing the order in which attributes are added to the antecedent of functional dependencies favours the quality of the results we obtain. Indeed,

as we have already discussed, our method privileges the addition of attributes that allow us to obtain functions that are “as well defined as possible”, by approximating the goodness to 0. This is because we try to construct an FD that resembles as much as possible a bijective function, mapping the clusters generated by the antecedent of the FD to the clusters generated by the consequent of the FD. This choice allows us to:

- discourage the addition of a UNIQUE attribute: indeed, that would make the rest of the antecedent useless, because that attribute alone determines the consequent of the FD;
- along the same line of thought, encourage the addition of attributes that make the “specificity” of the antecedent of the FD is as much as possible similar to the “specificity” of the consequent;
- support indexing and query optimization, because, when the method manages to find “invertible” FDs, not only the antecedent determines the consequent but also vice-versa; thus, an index built on the antecedent of an FD can be used to efficiently access the attributes in the consequent (if we know the correspondence between the clusters in the antecedent and the clusters in the consequent).

7. CONCLUSION

In this paper we proposed a new method for repairing FD violations that works at the intensional level: rather than changing the data, it repairs the FD by adding one or more attributes to its antecedent. To this aim we have used the notions of confidence and goodness of an FD, as measures to estimate if an FD is violated by the data and to what extent. In future we intend to extend the method to other kinds of constraints and to make a more extensive study on the parameters that influence the processing time and on the impact they have when examining a database.

ABSTRACT

Data profiling is the discipline of examining an unknown dataset for its structure and statistical information. It is a preprocessing step in a wide range of applications, such as data integration, data cleansing, or query optimization. For this reason, many algorithms have been proposed for the discovery of different kinds of metadata. When analyzing a dataset, these profiling algorithms are often applied in sequence, but they do not support one another, for instance, by sharing I/O cost or pruning information.

We present the holistic algorithm MUDS, which jointly discovers the three most important metadata: inclusion dependencies, unique column combinations, and functional dependencies. By sharing I/O cost and data structures across the different discovery tasks, MUDS can clearly increase the efficiency of traditional sequential data profiling. The algorithm also introduces novel inter-task pruning rules that build upon different types of metadata, e.g., unique column combinations to infer functional dependencies. We evaluate MUDS in detail and compare it against the sequential execution of state-of-the-art algorithms. A comprehensive evaluation shows that our holistic algorithm outperforms the baseline by up to factor 48 on datasets with favorable pruning conditions.

H.2.8 [Information Systems]: Database Applications; H.3.3 [Information Systems]: Information Search and Retrieval

General Terms

Algorithms, Performance, Theory

Keywords

data profiling, inclusion dependency, functional dependency, unique column combination

1. DEPENDENCY DISCOVERY

With the ever growing amount of digitally recorded information, the need to maintain, link, and query these information becomes increasingly hard to fulfill. For many applications, such as data mining, data linkage, query optimization, schema matching, or database reverse engineering, it is crucial to understand the data and, in particular, its structure and dependencies [13]. In biological research, for instance, scientists create large amounts of genome data that grow rapidly every year [2]. Originating from different genome sequencers, the data needs to be analyzed and linked to other datasets. This task requires knowledge of several structural properties of the data.

Usually, the reason why data becomes difficult to access is that metadata about the datasets' structure or their dependencies is missing. Therefore, various profiling algorithms have been proposed for the computationally intensive discovery of metadata, such as inclusion dependencies (INDs) [4, 8], unique column combinations (UCCs) [1, 9, 10, 16], and functional dependencies (FDs) [11, 14]. The algorithms SPIDER [4] for the discovery of INDs, DUCC [10] for UCCs and FUN [14] for FDs are among the most efficient algorithms in their respective problem domain. The idea of all these discovery algorithms is to reduce the tremendous search spaces with so called pruning rules: A pruning rule allows to infer the (in)validity of certain unchecked metadata candidates from already checked ones. Each algorithm, however, computes only one type of metadata. While this might be sufficient for some applications, most applications like data exploration or data integration require different types of metadata at the same time [13]. Therefore, current data profiling processes run several highly complex algorithms in a row. Considering that these algorithms and the metadata they discover have many commonalities, the sequential execution is a waste of time and resources.

Some existing profiling algorithms, such as HCA [1] or FUN [14], already leverage some knowledge about other types of metadata to reduce the discovery time (pruning). However, the combination of different profiling algorithms, i.e., a *holistic algorithm*, can utilize many more interleavings to increase its overall efficiency: First, it can facilitate new pruning rules using all collected information at once. In this way, fewer validity checks on the actual data are required. Second, it can share common costs like those required for I/O operations and iteration cycles. Third, it can combine similar data structures from different profiling tasks into one holistic data structure reducing overall memory consumption and initialization costs.

In this paper, we describe new inter-task pruning capabilities and analyze their impact on the algorithm’s runtime. We also develop and evaluate a novel holistic algorithm called MUDS, which jointly discovers unary INDs, minimal UCCs, and minimal FDs in one execution while facilitating all three opportunities for performance optimization mentioned above. If a dataset has favorable pruning conditions – which is true for most real-world datasets – MUDS improves upon the sequential execution of profiling algorithms by up to a factor of 48. In our evaluation, we investigate dataset characteristics that lead to good and poor runtime behavior.

Contributions. We first analyze INDs, UCCs, and FDs for their commonalities and examine state-of-the-art profiling algorithms (Section 2). We then discuss different approaches for holistic data profiling and possible pruning rules across profiling tasks (Section 3). Next, we describe how different types of FDs can be discovered or pruned if minimal UCCs are already known (Section 4). Based on the discovery and pruning techniques, we present the novel algorithm MUDS, which utilizes inter-task pruning rules (Section 5). MUDS derives FDs directly from discovered minimal UCCs and facilitates a new depth-first traversal strategy that is based on minimality pruning and the knowledge about non-dependencies (unlike previous level-wise approaches for FDs that solely rely on minimality pruning). Finally, we compare MUDS with the sequential execution of state-of-the-art algorithms and with a holistic adaption of the algorithms SPIDER and FUN (Section 6). Our evaluation shows that MUDS usually not only considerably outperforms the baseline algorithms but also outperforms common FD discovery algorithms on datasets with more than 10 columns.

2. PROFILING TASKS

For our holistic approach, we focus on three common and computationally intensive profiling tasks: The discovery of all unary inclusion dependencies, all unique column combinations, and all functional dependencies in a given dataset. This section defines the three tasks and explains one state-of-the-art algorithm for each of them. The chosen algorithms are among the most efficient algorithms for their specific task and exhibit favorable features to combine them into a holistic algorithm. At the end of this section, we compare the nature of the profiling tasks and their search space complexities.

2.1 Inclusion dependencies

An inclusion dependency (IND) $X \subseteq Y$ between attribute sets X and Y describes that the projection of Y contains all values of the projection of X , i.e., all values in X are also contained in Y . Attribute set X is called the *dependent* and Y is called the *referenced*. INDs with only one attribute in the sets X and Y are called *unary INDs*. Because only these unary INDs are of interest for the holistic discovery of other metadata types, we only consider them in our holistic algorithm. Without any loss of generality, we could discover n -ary INDs as well, but these would not contribute to the holistic discovery. We also artificially restrict the IND discovery to a single relation, because the two other metadata types UCCs and FDs are defined on only one relation. The search space for a relation with n attributes, hence, comprises $n \cdot (n - 1)$ unary IND candidates.

SPIDER is the currently most efficient algorithm for the detection of unary INDs. The algorithm developed by Bauckmann et al. [4] consists of two phases: A sorting phase and a comparison phase. In the first phase, SPIDER sorts the values of each column, eliminates duplicate values, and stores the sorted values in separate lists (Tables 1.1 and 1.2). In the second phase, SPIDER initially assumes that all attributes are included in one another. Then, it iterates simultaneously over the sorted lists in order to invalidate IND candidates (Tables 1.3 and 1.4). For the invalidation, SPIDER selects the group of attributes that all contain the currently smallest value. In our example A and C both contain w . By set intersection, the algorithm then excludes INDs from the candidates: The attributes in this group can only be included in one another, because they exclusively contain a value. So, A can still depend on C , but A cannot depend on B , because B does not contain w . The algorithm continues with next smallest values until only valid INDs remain.

1.			2.			3.			4.		
A	B	C	A	B	C	A	B	C	A	B	C
w	z	x	w		w	→w		→w	w		w
w	x	x	x	x	x	x	→x	x	→x	→x	→x
x	z	w	y			y			y		
y	z	z		z	z		z	z		z	z

Table 1: Example execution of Spider

2.2 Unique column combinations

A set X of attributes is a unique column combination (UCC) if the projection of X does not contain duplicates; otherwise, it is a non-unique column combination (non-UCC). UCCs are also called key candidates, because the values of the projection of a UCC uniquely define all records. X is a *minimal* unique column combination (minimal UCC) if it is a UCC and no proper subset of X is a UCC. The number of possible candidates for UCCs in a relation R with n attributes is $2^n - 1$. We can visualize the search space of UCC candidates as a lattice of attribute sets, i.e., a Hasse diagram (Figure 1). Each node represents a set of attributes and each edge a superset/subset relationship.

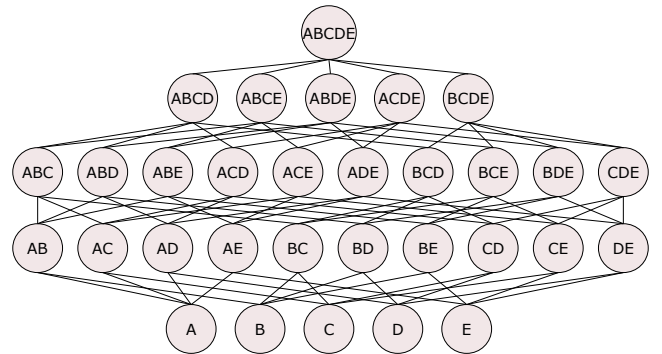

Figure 1: Attribute lattice for five columns

The DUCC algorithm is among the most efficient algorithms for detecting UCCs [10]. It applies a combination of depth-first and random walk strategies to traverse the lattice of UCC candidates. Thereby, DUCC uses the information about both discovered UCCs and non-UCCs for pruning.

The traversal starts from the bottom of the lattice. Every time the algorithm detects a non-UCC, it generates all direct supersets and picks one randomly as its next candidate; if the algorithm detects a UCC, the next candidate is a random direct subset. While traversing, DUCC prunes subsets of non-UCCs and supersets of UCCs from the search space, because subsets of non-UCCs are also non-UCCs, and supersets of UCCs cannot be minimal. It is possible that some column combinations remain unvisited after the random walk. The reason for such “holes” in the lattice is the combination of upwards and downwards pruning. DUCC identifies and fills these holes by comparing the found minimal UCCs with the complement of the found maximal non-UCCs.

During traversal, the algorithm has to check whether a column combination is a UCC or a non-UCC. This check is performed by constructing a position list index (PLI, also called stripped partition) for the column combination. A PLI is a list that contains sets of tuple ids [11]. These tuple ids belong to tuples of the column combination that contain the same value. If a PLI contains no id-set of size two or larger, the column combination contains no duplicate value and is, hence, unique. Because only id-sets of size two or larger are necessary for this test, all id-sets of size one can be removed, i.e., stripped from the PLI. So if the PLI is empty, all values are unique and the column combination is a UCC. To calculate the PLI for an unvisited lattice node AB , DUCC intersects the PLIs of the nodes A and B by pair-wise intersecting their id-sets.

2.3 Functional dependencies

Given a relation R , a functional dependency (FD) $X \rightarrow A$ between a set of attributes X and an attribute A exists if the values of X uniquely determine the values of A [6]. We call X the *left hand side* and A the *right hand side*. An FD is called trivial if $A \in X$. The FD is minimal if no proper subset of X determines A . A set of attributes X can determine multiple other attributes Y . In the following, we use the short notation $X \rightarrow Y$ to denote FDs with one or more right hand side attributes. In the lattice shown in Figure 1, every *edge* represents a potential FD. For example, the edge between ABC and $ABCD$ represents the FD candidate $ABC \rightarrow D$. To count all FD candidates for n attributes, we count the edges in each level k with $k = 1 \dots n$. Starting with attribute sets of size one, the sets are extended by one attribute in each level until the set in the highest level contains all attributes. In each level k we find $\binom{n}{k}$ nodes. Each node in level k can be connected to $n - k$ nodes in the next level without generating duplicate connections. The number of FD candidates in a relation with n attributes is therefore $\sum_{k=1}^n \binom{n}{k} \cdot (n - k)$.

Among the many FD discovery algorithms, FUN is one of the fastest algorithms [14]. FUN discovers FDs in a relation R by traversing the attribute lattice level-wise with a bottom-up strategy. While exploring the attribute lattice, FUN generates PLIs for each traversed attribute set. The algorithm then derives the cardinality of attributes and attribute combinations from their PLIs. This information is used to efficiently detect FDs by *partition refinement* as described in Lemma 1 (from [14]). In a relation R and a relation instance r , let $|X|_r$ denote the cardinality of the projection of X over r .

LEMMA 1. $\forall X \subseteq R, A \in R: X \rightarrow A \Leftrightarrow |X|_r = |X \cup \{A\}|_r$

FUN classifies column combinations into *free sets* and *non-free sets*. A free set X contains only those attributes that are not functionally dependent on any other attribute in X . A non-free set contains at least one functionally dependent attribute. Definition 1 describes the set of free sets \mathcal{FS}_r :

DEFINITION 1. The set of free sets \mathcal{FS}_r is defined as $\forall X \subseteq R: X \in \mathcal{FS}_r \Leftrightarrow \nexists X' \subset X: |X'|_r = |X|_r$.

The FUN algorithm has a pruning advantage in comparison to other FD algorithms like TANE [11], because it omits certain PLI intersect operations and retrieves missing cardinality information from a node’s child nodes. So instead of performing a PLI intersect, FUN infers the cardinality of a pruned non-free set with a recursive look-up in the non-free set’s subsets.

2.4 Comparison of profiling tasks

The discovery of INDs inherently differs from the discovery of UCCs and FDs: For INDs, the attribute values are of interest whereas for FDs and UCCs only the *position* of equal values is relevant. Hence, UCC and FD algorithms use quite different data structures than IND algorithms; these data structures do not allow the reconstruction of values (e.g., PLIs), but improve the algorithms’ efficiency. However, several relationships between FDs and UCCs can be used for pruning (see Sec. 3).

To determine the complexity of a holistic algorithm, we need to inspect the search spaces of the different sub-tasks: A relation with n attributes contains $n \cdot (n - 1)$ unary IND candidates. IND discovery is, hence, in $O(n^2)$. In the same relation, the number of UCC candidates is $\sum_{k=1}^n \binom{n}{k}$, which places the search space of UCCs in $O(2^n)$. The number of FD candidates is $\sum_{k=1}^n \binom{n}{k} \cdot (n - k)$ so that FD discovery is in $O(n \cdot 2^n)$. The search space for FDs, therefore, clearly dominates the overall discovery cost. The exponential search spaces of UCCs and FDs in particular dominate the quadratic search space of unary INDs. Our evaluation in Sec. 6.4 shows that the time spent on IND discovery is indeed negligible in comparison to the time spent on UCC and FD discovery. For this reason, INDs can best be calculated as a byproduct in the starting phase of a holistic algorithm.

3. HOLISTIC APPROACH

As we described in Section 2.4, IND discovery differs greatly from the discovery of UCCs and FDs. Therefore, INDs are discovered while the input data is read and the values are still accessible. The discovery uses the SPIDER algorithm and mainly profits from sharing its I/O costs with the UCC and FD algorithms, i.e., the data is read only once and then used for the discovery of all three types of metadata. SPIDER additionally profits from the initial PLI-construction that is performed for both the UCC and FD discovery: At construction time, PLIs map values to positions so that SPIDER can retrieve duplicate-free value lists from this mapping, which are more efficient to sort.

If the input dataset contains two identical rows, i.e., duplicate records, then it cannot contain any UCC and, hence, most inter-task pruning rules would not apply. Therefore, we assume that duplicate records, which are forbidden in most database systems anyway, have been removed in a pre-processing step.

We now discuss three basic approaches for the holistic discovery of INDs, UCCs, and FDs.

3.1 FDs first

By discovering minimal FDs first, we can derive all minimal UCCs from the discovered FDs [15]. The UCC inference follows Lemma 2. Under the assumption that each row in R is distinct, every column combination that functionally determines all other attributes of the relation R is a key in R and, hence, a UCC:

LEMMA 2. $\forall U \subseteq R : U \rightarrow R \setminus U \Rightarrow U$ is a UCC

Thus, all UCCs can be inferred from the set of minimal FDs. Without describing an actual algorithm for UCC inference, it is clear that the inference and minimization of UCCs introduces an additional overhead. As several FD discovery algorithms (e.g., FUN and TANE) exist that already find all minimal UCCs while discovering FDs, we do not pursue this FDs-first approach for a holistic algorithm. Instead, we focus on approaches that improve the overall runtime by avoiding this additional overhead and by leveraging pruning.

3.2 FDs and UCCs simultaneously

To discover FDs and UCCs simultaneously, we analyzed several FD discovery algorithms and evaluated their extensibility towards UCC discovery. As already described in Sections 2.3 and 2.4, FUN uses an attribute lattice for pruning that is very similar to DUCC's way of calculating minimal UCCs. Furthermore, FUN traverses all unpruned free sets. The following Lemma 3 shows that all minimal UCCs are "free sets" in FUN's sense. Therefore, FUN must traverse the minimal UCCs for FD discovery, enabling the discovery of minimal UCCs with little impact on the overall runtime. In a relation instance r , \mathcal{U}_r is the set of all minimal UCCs in r .

LEMMA 3. $\forall U \in \mathcal{U}_r : U \in \mathcal{FS}_r$

PROOF. Let $X \in \mathcal{U}_r$ be a minimal UCC and let $X \notin \mathcal{FS}_r$ be a non-free set. According to Definition 1, $X' \subset X$ with $|X'|_r = |X|_r$ exists. X' has the same distinct count as X . Therefore, X' is a UCC. This contradicts the initial assumption that X is a *minimal* UCC and, therefore, no subset of the minimal UCC X can be a UCC. \square

In the original version of FUN, minimal UCCs are detected and used for key-pruning, which is a common pruning rule for FD discovery: The supersets of UCCs can be pruned, because they cannot be the left hand side of a minimal FD. This pruning rule is applied in FD discovery algorithms like TANE and FUN. With small adaptations, it is possible to store the minimal UCCs and return them when the algorithm terminates. This does not impair the runtime of FUN, because no further checks are necessary. We implemented this algorithm and call it HOLISTIC FUN.

3.3 UCCs first

If a holistic algorithm first discovers all minimal UCCs, it can leverage this information for the discovery of minimal FDs, due to the key-pruning rule. As we explain in Section 4.1, many left hand sides of minimal FDs are subsets of minimal UCCs. This observation can be used to discover and minimize relevant FDs faster. It can further be used for pruning, because applying this rule reduces the number of traversed column combinations in comparison to level-wise FD discovery algorithms. Several rules can derive the invalidity of certain FDs from the known minimal UCCs. We present these rules in more detail in Section 4 and use them in the implementation of our algorithm MUDS in Section 5.

4. DISCOVERING FDS BASED ON UCCS

In this section, we present pruning and inference rules that allow for a fast FD discovery based on known UCCs. These rules lay the foundation for our MUDS algorithm described in Section 5. We show in Section 6 that an algorithm using these rules is usually faster than current state-of-the-art FD discovery algorithms. We first describe the UCC-based pruning rules for FDs. The following three subsections then match the three sub-algorithms of MUDS' FD discovery: *minimize FDs*, *calculate $R \setminus Z$* , and *shadowed FDs*.

Figure 2 categorizes the attributes of a relation R into the set $Z := \bigcup_{U \in \mathcal{U}} U$, which is the union of all minimal UCCs, and the set $R \setminus Z$, which contains all columns that are not contained in any minimal UCC. In the following, we describe the two situations, shown in Figure 2, where the non-existence of functional dependencies can be inferred from the set of UCCs.

Figure 2: Possible FDs in R with two minimal UCCs

1. FDs fully contained in a minimal UCC: An FD cannot exist if it is fully contained in a minimal UCC (both left and right hand side are subsets of the same minimal UCC). The right hand side of an FD carries only information that could be inferred from the left hand side. Therefore, if a functional dependency existed that is contained in a minimal UCC, the right hand side can be removed from the minimal UCC without changing the uniqueness property. This contradicts the minimality of the UCC.

2. FDs with a lhs in $R \setminus Z$ and rhs in Z : Consider an FD $X \rightarrow A$ with a left hand side $X \subseteq R \setminus Z$ and a right hand side $A \in U$ with $U \in \mathcal{U}$. A is determined by X ; hence, A can be substituted by X in U . This yields at least one unique $U_{\text{subs}} = X \cup U \setminus A$. Thus, a minimal unique U_{min} must exist that is subset of U_{subs} . U_{min} must still contain one or more attributes of X (otherwise U could not have been minimal, as A could have been omitted). It follows that a part of X is contained in a minimal UCC, which contradicts the proposition that X is a subset of $R \setminus Z$. Thus, no such FD may exist.

In the following, we present rules and operations that enable the discovery of FDs using the two pruning rules described above. In Section 4.1, we first describe how to discover FDs that have left and right hand sides in overlapping minimal UCCs.

4.1 FDs between minimal UCCs

A UCC functionally determines all other columns of the same relation. Thus, FDs can be inferred from a discovered UCC. Not all of these FDs are minimal. To find the minimal FDs, the substitution pruning rule can be applied:

Substitution rule: For every FD that has an attribute of a minimal UCC as right hand side, we can infer a new UCC, by substituting that attribute in the UCC with the

left hand side of the FD. If the inferred UCC does not exist, the corresponding FD cannot hold and must not be checked. This insight is used to validate FD candidates by checking for corresponding UCCs. For instance, given a relation $R = \{A, B, C, D, E, F\}$, the minimal UCCs ABC and DEF , and the FD candidate $BC \rightarrow D$ that we need to check. The UCC $BCEF$ follows by substituting D with BC . Now, a subset of $BCEF$ that is also a proper superset of EF must be a minimal UCC. As this minimal UCC does not exist, we know that the FD $BC \rightarrow D$ cannot exist.

It follows that valid FDs between minimal UCCs must fulfill the following condition: The left hand side and the right hand side of valid FD must be subsets of different and intersecting minimal UCCs. We use this insight in the MUDS algorithm, using an operation that we call *connector lookup*. We describe this operation in detail in Section 5.1.

4.2 FDs with right hand sides in $R \setminus Z$

TANE and similar algorithms for FD discovery traverse the attribute lattice bottom-up. In the traversal, these algorithms utilize pruning rules based on the minimality of dependencies. If a left hand side is known to yield only non-minimal FDs (e.g., it already contains an FD), this left hand side is pruned from the lattice and the traversal is continued with a reduced candidate set (upwards pruning). We now propose a traversal strategy that operates similarly to the random walk strategy in the UCC discovery algorithm DUCC. For this traversal, pruning of subsets (downwards pruning) is necessary. This pruning is based on a property of FDs: If $X \rightarrow A$ does not hold, A cannot be functionally dependent on any subset of X .

LEMMA 4. $\forall X \subseteq R, \forall A \in R, \forall X' \subseteq X : X \rightarrow A \Rightarrow X' \rightarrow A$

Lemma 4 can be used to prune downwards. To facilitate this pruning, we traverse a *sub-lattice* for each possible right hand side. A sub-lattice is a lattice created for a specific right hand side attribute, which is omitted from the lattice. The nodes in the sub-lattice contain only the different left hand side candidates. All sub-lattices for an exemplary relation with columns A, B, C, D are shown in Figure 3. In the sub-lattices, the above mentioned pruning rule applies, because of the fixed right hand side.

Figure 3: Sub-lattices for the right hand side columns A, B, C, and D

The example in Figure 3 shows that some column combinations are represented in multiple lattices. The column combination CD , for example, is contained in the first and in the second lattice. Such column combinations are only fully pruned, i.e., we do not need to calculate their PLIs, if the column combination is pruned in all sub-lattices. In the best case, entire sub-lattices can be pruned.

Section 5.2 presents an algorithm that leverages the sub-lattice pruning. The algorithm also assures that only columns of $R \setminus Z$ are used as right hand sides of FD candidates.

4.3 Shadowed FDs

Section 4.1 describes how FDs can be deduced from minimal UCCs. Unfortunately, not all minimal FDs can be found in this way. If a minimal UCC U and a column combination $X \subseteq U$ exist and the FD $X \rightarrow A$ holds, a column A may be *shadowed* in U : A can be part of a left hand side with only other columns of U . As our algorithm would not consider this left hand side, we call the left hand side and the resulting FD *shadowed*. To still find all minimal FDs, a post-processing step is needed that explicitly checks all left hand sides containing attributes from different minimal UCCs or even $R \setminus Z$. We explain the algorithm in Section 5.3 but first give an example of how shadowed attributes arise:

Let BCD , CDE , and AD be the only minimal UCCs in a dataset for the relation $R = \{A, B, C, D, E\}$. Suppose that the minimal UCCs directly contain the minimal FDs, i.e., $BCD \rightarrow AE$, $CDE \rightarrow AB$, and $AD \rightarrow BCE$. Now, assume that there is an additional minimal functional dependency $AC \rightarrow B$. The inference rule from Section 4.1 cannot find this FD, because the left hand side AC cannot be deduced from the minimal UCCs BCD , CDE , or AD . Thus, $AC \rightarrow B$ is never checked. The existence of the minimal FDs $BCD \rightarrow A$ indicates that A is shadowed in every subset of BCD . C is shadowed analogously in every subset of AD by the minimal FD $AD \rightarrow C$. Therefore, every attribute that is determined by a subset of BCD or AD may also be determined by a subset of $ABCD$ or ACD containing A and C .

For each minimal FD $Y \rightarrow W$, we must find all shadowed attributes S . The shadowed attributes are added to the left hand side of the functional dependency. This results in the FD $Y \cup S \rightarrow W$, which holds, but is not necessarily minimal. The FD must be minimized and we provide pseudo-code for a minimization algorithm in Section 5.3.

5. THE MUDS ALGORITHM

In this section, we develop a holistic profiling algorithm called MUDS, which jointly discovers unary INDs, minimal UCCs, and minimal FDs facilitating pruning across the different profiling tasks. The acronym MUDS is a composition of the algorithms key features: “Mu” for Minimizing UCCs, “D” for the Depth-first approach that is used to find FDs with right hand side in $R \setminus Z$, and “s” for shadowed FDs.

The algorithm uses the following execution strategy: While reading the input dataset, MUDS directly applies the SPIDER algorithm described in Section 2.1 to calculate INDs (one shared I/O operation). Since this algorithm already requires to read and sort all records, MUDS also builds the PLIs in this step. Afterwards, MUDS runs the DUCC algorithm, described in Section 2.2, using the previously calculated PLIs to identify all minimal UCCs. Finally, it executes a novel FD discovery algorithm that is based on the concepts explained in Section 4. The FD discovery takes advantage of the known minimal UCCs (inter-task pruning) and the already calculated PLIs (shared data structures).

The FD discovering part of MUDS consists of three phases: In the first phase, MUDS discovers the FDs among overlapping minimal UCCs (Section 5.1). In the second phase, the algorithm finds FDs with right hand sides in the set of columns that are non-minimal UCCs ($R \setminus Z$) (Section 5.2). In the third phase, MUDS discovers and minimizes the remaining FDs that have a shadowed left hand side (Sec-

tion 5.3). Because the FD validations in the MUDS algorithm perform many superset look-ups to find minimal UCCs for left hand side column combinations, we introduce a prefix tree of UCCs that ensures fast look-up times (Section 5.4).

5.1 FDs in connected minimal UCCs

MUDS is a “Unique Column Combinations First” algorithm. So it first discovers all minimal UCCs to use them for the FD discovery. So when starting the FD discovery, all minimal UCCs are already known. Now, the first part of MUDS’ FD discovery analyzes only those FDs whose left and right hand side columns are included in minimal UCCs. For an FD $X \rightarrow Y$, we call the complete set of functionally determined attributes Y the *closure* of X . Suppose U is a minimal UCC in the relation R ; then, the closure of U is R , because U functionally determines all other attributes. It is possible that some of the attributes in the closure of U are non-minimally determined, which means that they are also determined by a subset of U . To minimize the left hand sides of the non-minimal FDs, we check whether the direct subsets of U functionally determine attributes in the closure. In the following, we present an algorithm that minimizes the left hand sides, starting from the minimal UCCs in a top-down manner.

Recursive minimization. In order to minimize the left hand sides of the FDs deduced from minimal UCCs, we start from the UCCs themselves and recursively analyze subsets of the UCCs. Algorithm 1 shows the pseudocode for the recursive minimization. MINIMIZEFDs takes two input parameters: the set \mathcal{U} of all minimal UCCs discovered in the previous step and the union Z of all attributes that appear in at least one minimal UCC. The algorithm iterates over all minimal UCCs $U \in \mathcal{U}$, generates FD candidates from them, and then creates minimization tasks for the generated FDs (lines 2-3). We use tasks and a queue of tasks to avoid recursive method calls, which uses heap memory instead of stack memory.

For every task, we know the valid right hand sides from the parent closure, but the minimality of these FDs is not yet known. To determine the minimal right hand sides, MINIMIZEFDs iterates over the left hand side’s direct subsets and checks which FDs are also valid in the subsets $U' \subset U$ (line 8). To this end, the algorithm determines the subset’s connector $C := U \setminus U'$ and performs the connector look-up (lines 9-10). We describe this connector look-up below. Then, MINIMIZEFDs tests the candidate FDs using partition refinement (line 11). If it finds an FD, MINIMIZEFDs removes the corresponding attribute from the closure of the current left hand side, because the left hand side cannot be minimal (line 12). Finally, we create new tasks for all direct subsets with the valid right hand side (line 15). The valid right hand sides contain all attributes that are still functionally determined by the current subset. After checking the FDs in all subsets, the closure of the current left hand side contains only those right hand sides for which the current left hand side is minimal. The MINIMIZEFDs function then outputs these minimal FDs (line 16).

Connector look-up. MUDS generates the right hand side candidates using an operation that we call *connector look-up*. The connector look-up ensures that the left and right hand side are subsets of different minimal UCCs and that the minimal UCCs overlap. We already discussed the princi-

Algorithm 1 Calculate FDs from minimal UCCs

Require: minimal UCCs \mathcal{U} , union of all minimal UCCs Z

```

1: function MINIMIZEFDs( $\mathcal{U}$ ,  $Z$ )
2:   for  $U \in \mathcal{U}$  do
3:      $tasks.add((lhs \leftarrow U, rhs \leftarrow Z \setminus U, mUcc \leftarrow U))$ 
4:    $FDs \leftarrow \text{new Map}<\text{ColumnComb}, \text{ColumnComb}>()$ 
5:   while  $!tasks.isEmpty()$  do
6:      $task \leftarrow tasks.remove()$ 
7:      $currentRhs \leftarrow task.rhs$ 
8:     for  $lhsSubset \in task.lhs.getDirectSubsets()$  do
9:        $connector \leftarrow task.mUcc \setminus lhsSubset$ 
10:       $potentialRhs \leftarrow \text{connectorLookup}(connector \setminus$ 
         $\text{getImpossibleColumns}(lhsSubset))$ 
11:       $validRhs \leftarrow \text{checkFDs}(task.lhs, potentialRhs)$ 
12:       $currentRhs \leftarrow currentRhs \setminus validRhs$ 
13:      if  $validRhs.isEmpty()$  then
14:        continue
15:       $tasks.add((lhs \leftarrow lhsSubset, rhs \leftarrow validRhs,$ 
         $mUcc \leftarrow task.mUcc))$ 
16:       $FDs[lhs] \leftarrow FDs[lhs] \cup currentRhs$ 
17:   return  $FDs$ 
```

ples used for this operation in Section 4.1. We now describe the connector look-up in an example shown in Table 2. To perform the connector look-up for a column combination, MUDS splits the minimal UCCs into a potential left hand side and a connector. In our example, we split the minimal UCC AFG into the potential left hand side A and the connector FG . Then, we use the connector to perform a look-up on the minimal UCCs: All minimal UCCs that are supersets of the connector, are candidates for the right hand side. Table 2 lists all minimal UCCs of our example in the *mUCCs* column. In the *matched* column, Table 2 depicts the retrieved UCCs. The subset of the matching UCCs that is not the connector is printed in bold font. The result of the look-up is the union of these columns; these columns serve as right hand sides for the next FD candidates.

<u>mUCCs</u>	<u>matched</u>	
<u>AFG</u>	<u>AFG</u>	union: ABCDE
<u>BDFG</u>	BDFG	
<u>DEF</u>	-	
<u>CEFG</u>	CEFG	

Table 2: Connector look-up with connector FG

After the connector look-up, the algorithm removes all left hand side columns of the new FD candidate from the right hand side columns, because trivial FDs do not need to be checked. So in the example, we would remove A from the union $ABCDE$. Additionally, the algorithm checks whether the union of the left and right hand side is a subset of a minimal UCC; such dependencies cannot exist, because minimal UCCs cannot contain FDs in themselves.

In the following, we describe the minimization of FDs for the example minimal UCC AFG . Figure 4 depicts the traversed graph. Note that for conciseness, we describe the recursion in only one branch. At first, MUDS initializes the closure of the minimal UCC AFG to $R \setminus \{AFG\}$, which in this case is $BCDE$. Then, the algorithm splits AFG into its direct subsets, i.e., left hand sides for new FD candidates,

and the connector (the connector is shown in round brackets). At node AF , MUDS performs the connector look-up, which yields the potential right hand sides BD . By checking the FDs $AF \rightarrow B$ and $AF \rightarrow D$ using partition refinement (see Section 2.3), the algorithm finds that both FDs still hold. Therefore, it can remove the FDs' right hand sides from the superset closure in node AFG , because these cannot be minimal at AFG . Then, MUDS computes the direct subsets of AF and again performs the connector look-up. For the column A , the look-up yields BD , whose dependencies are then tested. In the test, the algorithm finds only $A \rightarrow B$ to be valid, which invalidates the minimality of the parent FD $AF \rightarrow B$. After completing an entire level, MUDS outputs the previous level's remaining right hand sides as valid minimal FDs. The algorithm terminates when no potential right hand sides remain or the list of direct subsets is empty. Upon termination, the algorithm has discovered and minimized all FDs among connected minimal UCCs.

Figure 4: Example for recursive FD minimization

5.2 Graph traversing for $R \setminus Z$

This section focusses on those FDs whose right hand side is in $R \setminus Z$. The set $R \setminus Z$ contains all columns that are not element of any minimal UCC. Hence, the previous step did not find these FDs. In contrast to existing FD discovery algorithms, we can restrict possible right hand sides to columns that belong to $R \setminus Z$, because the previous step has already found all minimal FDs with right hand side in Z . Therefore, not all columns in the relation need to be analyzed as potential right hand sides.

As discussed in Section 4.2, MUDS uses one sub-lattice for each potential right hand side to profit from downwards pruning. The algorithm traverses each sub-lattice using a random walk strategy that is based on the traversal strategy of the UCC discovery algorithm DUCC, which we already introduced in Section 2.2: Suppose that we search for FDs with right hand side A . MUDS first constructs the lattice of left hand side candidates for A using the attributes $R \setminus A$. Then the random walk starts at a random seed node on the first level of this lattice. At each node, we check if the column combination in that node determines A .

Suppose we are at the node that contains the column combination X . If X determines A , we continue the traversal by choosing a random subset of X , because the discovered FD $X \rightarrow A$ might not be minimal. All supersets of X also determine A , but are minimal. Therefore, we prune all supersets of X . If the column combination X does not determine A , the next traversal step chooses a random superset of X . All subsets of X can then be pruned, because they cannot determine A (Lemma 4). As noted in Section 2.2, the lattice might contain holes of unvisited nodes, which have to be

discovered in the end. For this task, MUDS uses the same approach as DUCC [10].

The mayor difference of this traversal strategy to DUCC's traversal strategy lies in the check that decides which nodes are traversed next: DUCC checks the uniqueness of the node's column combination by inspecting the cardinality of the node's PLI; MUDS checks whether the node's column combination functionally determines the sub-lattice's right hand side A by testing for partition refinement as described in Lemma 1 in Section 2.3.

Before MUDS starts the graph traversal for $R \setminus Z$, it has already determined several minimal FDs (see Section 5.1). These known FDs are used for additional pruning in the lattice: The combination of a left hand side with its right hand side can never be the left hand side of an already known minimal FD (see Section 2.3). The random walk on a sub-lattice terminates when all candidates are checked or pruned. Then, MUDS continues with the remaining sub-lattices until all FDs with right hand sides in $R \setminus Z$ are found.

5.3 Shadowed FD discovery

The two previously described sub-algorithms of MUDS' FD discovery part do not yet find all FDs. This is due to the fact that some FDs are shadowed (see Section 4.3). In the following, we present an algorithm that finds and minimizes these shadowed FDs by first extending and then minimizing the left hand sides of already discovered FDs.

Shadowed FD discovery: Algorithm 2 shows the discovery of the (not necessarily minimal) shadowed FDs. At first, the algorithm calculates the potentially shadowed columns. The columns are shadowed, because they occur in a right hand side of an FD and, thus, are not discovered when the algorithm deduces the FDs from UCCs in a previous step.

To find the missing FDs, the algorithm iterates over all previously discovered FDs in line 2 of Algorithm 2. For each FD, the algorithm iterates over the subsets in line 3 and creates a connector in line 4 that is used for a lookup of potentially shadowed columns in line 5. With these shadowed columns, the algorithm creates a new left hand side from the union of the current left hand side and the shadowed columns in line 6. The FD $newLhs \rightarrow fd.rhs$ obviously holds, because $fd.lhs \rightarrow fd.rhs$ holds and $newLhs = fd.lhs \cup shadowedRhs$. However, the FD $newLhs \rightarrow fd.rhs$ is not minimal and FDs that were previously not discovered might be deduced by minimizing the FD $newLhs \rightarrow fd.rhs$. $newLhs$ can contain many columns and be larger than UCCs. Thus, the amount of columns can be reduced prior to the minimization of the FD. This is a powerful pruning step, which is shown in line 7-8 of Algorithm 2. The

Algorithm 2 Discover shadowed FDs

Require: $map(lhs, rhs)$ of minimal FDs , minimal UCCs \mathcal{U}

```

1: procedure DISCOVERSHADOWEDFDs( $FDs, \mathcal{U}$ )
2:   for  $fd \in FDs$  do
3:     for  $subset \in fd.lhs.getAllSubsets()$  do
4:        $connector \leftarrow fd.lhs \setminus subset$ 
5:        $shadowedRhs \leftarrow FDs[connector]$ 
6:        $newLhs \leftarrow fd.lhs \cup shadowedRhs$ 
7:       for  $reduceLhs \in removeUCCs(newLhs, \mathcal{U})$  do
8:          $shadowedTasks.add(reduceLhs, fd.rhs)$ 
9:   minimizeFDs( $shadowedTasks$ )
```

Algorithm 3 Remove UCCs from the left hand side

Require: column combination to minimize lhs , minimal UCCs \mathcal{U}

```
1: function REMOVEUCCs( $lhs$ ,  $\mathcal{U}$ )
2:    $reducedLhs \leftarrow \{\}$ 
3:    $tasks.add(\langle pos \leftarrow 0, remCol \leftarrow \{\} \rangle)$ 
4:    $subsetUniques \leftarrow \mathcal{U}.getSubsetsOf(lhs)$ 
5:   while  $!tasks.isEmpty()$  do
6:      $task \leftarrow tasks.remove()$ 
7:     if  $task.pos \geq subsetUniques.size()$  then
8:        $reducedLhs.add(lhs \setminus task.remCol)$ 
9:       continue
10:     $unique \leftarrow subsetUniques[task.pos]$ 
11:    if  $(task.remCol \cap unique).isEmpty()$  then
12:       $tasks.add(\langle pos \leftarrow task.pos + 1,$ 
13:                 $remCol \leftarrow task.remCol \rangle)$ 
14:      continue
15:    for  $column \in unique.columns$  do
16:       $tasks.add(\langle pos \leftarrow task.pos + 1,$ 
17:                 $remCol \leftarrow task.remCol \cup column \rangle)$ 
18:  return  $reducedLhs$ 
```

method *removeUCCs()* compares the FD to the previously discovered UCCs. If *newLhs* contains at least a single UCC, a part of the UCC is removed and multiple *reducedLhs* are returned that do not contain any UCC. This is possible because no left hand side that contains a UCC can yield a minimal FD. This approach allows the algorithm to skip steps in the minimization of the FD, because the initial left hand sides are already smaller. In line 9, the algorithm minimizes the reduced left hand sides. After this step, all FDs in the dataset are discovered. In the following, we describe the methods *removeUCCs()* and *minimizeFDs()* in detail.

Shadowed FD pruning: As previously described, we are not interested in left hand sides that contain UCCs, because they cannot yield minimal FDs. Algorithm 3 shows the minimization of left hand sides by removing parts of UCCs. The resulting left hand sides do not contain any UCC. For a single non-minimized left hand side multiple reduced left hand sides may be generated.

We use tasks and a queue to avoid recursive method calls that is shown in line 3. Then, the algorithm calculates all UCCs that are contained in the left hand side in line 4. For each task, we save the next UCC that must be removed (*pos*) and the columns that should be removed from the initial left hand side to create a UCC-free left hand side (*remCol*). The algorithm iterates over the tasks in line 5-15. Lines 7-9 show a task that already iterated over all contained UCCs. Thus, the calculation of the reduced left hand side is finished and the reduced left hand side is added to the result in line 8. If at least a single UCC must be removed from the current left hand side, the algorithm obtains this UCC in line 10. Lines 11-13 check if the current UCC is completely removed due to the columns in *remCol*. If this is the case, MUDS continues with the next UCC by adding the task with an increased *pos* index in line 12. Lines 13-15 show the actual removal of columns. The algorithm iterates over the columns in the UCC in line 14. For each column, a new task is generated in line 15, where the current column is removed. When all tasks are processed, the algorithm returns the reduced left hand sides in line 16.

Algorithm 4 Discover and minimize potential FDs

Require: shadowed Tasks $tasks$, map(lhs, rhs) of minimal functional dependencies FDs

```
1: procedure MINIMIZEFDs( $tasks$ ,  $FDs$ )
2:   while  $!tasks.isEmpty()$  do
3:      $task \leftarrow tasks.remove()$ 
4:      $currentRhs = task.rhs$ 
5:     for  $subset \in task.lhs.getDirectSubsets()$  do
6:        $validFD \leftarrow checkFDs(subset, task.rhs)$ 
7:       if  $validFDs.isEmpty()$  then
8:         continue
9:        $currentRhs \leftarrow currentRhs \setminus validFDs$ 
10:       $tasks.add(\langle lhs \leftarrow subset, rhs \leftarrow validFDs \rangle)$ 
11:     $FDs[task.lhs] \leftarrow FDs[task.lhs] \cup currentRhs$ 
```

Shadowed FD minimizing: MUDS calls Algorithm 4 in Algorithm 2 to minimize FDs. The algorithm also uses a task queue to avoid recursive method calls. For every shadowed FD task containing a potential left and right hand side, MUDS generates all direct left hand side subsets (line 5). These subsets might already determine the right hand side. Afterwards, the algorithm checks, which FDs actually hold on the current subset's left hand side and then removes these dependencies from the superset's right hand side, because they are not minimal (lines 6-9). Then, MUDS creates new tasks for all direct subsets (lines 10). The set of minimal FDs is updated with the known superset's minimal FDs (line 11). When all tasks have been processed, the algorithm terminates. At this stage, all shadowed FDs have been discovered and minimized.

5.4 Subset pruning tree

As described in Section 5.3, MUDS also finds shadowed FDs. For each left hand side X , it needs to look-up all minimal UCCs that are subsets of X . The naïve implementation of this operation iterates over the list of minimal UCCs and performs a subset check for each minimal UCC. With an increasing number of attributes, the number of minimal UCCs increases as well, which makes this operation increasingly expensive. Therefore, we organize all minimal UCCs in a prefix tree that guarantees an efficient look-up of UCC subsets.

The concept of prefix trees was first presented by De La Briandais [7]. For the construction of our prefix tree, we assume that the columns in all column combinations are sorted (e.g. by their position in the dataset). Figure 5 depicts an exemplary prefix tree for UCCs. Level 1, which is the root node of the prefix tree, stores all columns that occur as the first column in any column combination. For each entry in level 1, a node in level 2 may exist. These nodes store the second columns of column combinations that share the same first column. This pattern continues for the other levels. The last column of a column combination can be identified as an entry that has no child node.

The MUDS algorithm uses the prefix tree to efficiently find subsets of minimal UCCs: Given a column combination X , we need to find all subsets of X that are contained in the prefix tree. To find them, we iterate over the sorted columns of X . For each column in X , we check whether the column is contained in level 1 of the prefix tree. If the column is not contained, we discard that column and continue with the

Figure 5: Prefix tree for seven column combinations

next column of X . If it is contained, we visit the associated node in level 2. There, we perform the same check with the remaining columns of X . Then, we go to level 3 and so on. Two conditions can stop the search: First, we find a matching node entry that has no associated node in the next level. This means that we found a subset of X . Second, there are no remaining columns in X , because we discarded all of them, but we have not reached the end of a path in the prefix tree. Then, the current path does not lead to a valid subset of X . In both cases, we need to trace back and start over with the remaining columns of X .

6. EVALUATION

We compare MUDS (Sec. 5), HOLISTIC FUN (Sec. 3.2), and the composition of baseline algorithms (Sec. 2) using the Metanome data profiling framework¹. The framework provides a standardized execution environment for pre-packaged profiling algorithms. In this way, common tasks like file I/O, user interaction, and result handling are decoupled from the algorithms allowing for fair comparisons. Metanome and all algorithms use OpenJDK 1.7 64-Bit. We show that the algorithms have different characteristics and sweet spots, but that MUDS is preferable in general.

Hardware. We execute our experiments on a Dell PowerEdge R620 with CentOS 6.4. The machine has 128 GB DDR3 RAM, of which 120 GB are assigned to the Java virtual machine, and two Intel Xeon E5-2650 (2.00 GHz, Octa-Core) CPUs. Because the implementations of our algorithms are all single threaded, only one of the cores is actually used.

Datasets. For the row scalability experiment in Section 6.1, we use the Universal Protein Resource² (*uniprot*) dataset. It is a public dataset about protein sequences and their functions and contains 539,165 rows and 223 columns. For the column scalability experiment in Section 6.2, we use the *ionosphere* [3] dataset. This dataset contains radar data of the ionosphere and features 351 rows and 34 columns (and many dependencies). Our third dataset, the North Carolina Voter Registration Statistics³ (*ncvoter*) dataset, contains non-confidential data about 7,503,575 voters from North Carolina and features 94 columns. We use this dataset for the evaluation in Section 6.4. For our experiments described in Section 6.3, we use additional real world datasets from the UCI machine learning repository [3]. The section also compares the performance of MUDS with the

performance of TANE [11], the most popular FD discovery algorithm, to show that MUDS can also compete with non-holistic FD algorithms. Finally, we discuss dataset properties that MUDS' FD discovery is optimized for in Section 6.5.

6.1 Scalability on rows

In the following experiment, we evaluate the scalability of our algorithms MUDS and HOLISTIC FUN with respect to the number of rows in the input dataset and compare them to the baseline algorithm, which is the sequential execution of SPIDER, DUCC, and FUN. Because of its length, the *uniprot* dataset is best suited for row-scalability experiments. Figure 6 depicts the execution times of the different algorithms on *uniprot* with ten columns while varying the dataset's number of rows.

Figure 6: Scalability with regard to the number of rows on the *uniprot* dataset

The measurements show that all three algorithms scale almost linearly with the number of rows. On this particular dataset, HOLISTIC FUN is the fastest algorithm; it is about 1/3 faster than the baseline, because HOLISTIC FUN shares the cost for I/O among the three profiling tasks and discovers UCCs directly with the FDs. MUDS, on the contrary, is the slowest algorithm on *uniprot*, because the discovery of shadowed FDs is particularly expensive on this dataset; if many shadowed FDs are to be discovered, the costs for this step also scale linearly with the number of rows.

6.2 Scalability on columns

The following experiment evaluates the algorithms with regard to the number of columns: Using the *ionosphere* dataset, we successively include more and more columns from the original dataset in each run. The *ionosphere* dataset is particularly interesting for column-scalability experiments, because it contains many and large FDs – a challenge for any FD discovery algorithm and a test of its pruning capabilities. The results are shown in Figure 7, which also presents the number of discovered FDs in the dataset.

The experiment shows that the execution times of all three algorithms scale exponentially with the number of columns, which is due to the fact that the search space for UCCs and FDs also grows exponentially. However, MUDS scales clearly better with the number of columns on the *ionosphere* dataset than both HOLISTIC FUN and the baseline, because due to the UCC-first discovery approach MUDS searches a much smaller search space and the number of shadowed FDs is manageable on *ionosphere*. The baseline and HOLISTIC

Figure 7: Scalability over the number of columns on the *ionosphere* dataset.

FUN both spend 99% of their runtime on FD discovery for 23 columns, which gives MUDS’ improved FD discovery a significant advantage. For the same reason, HOLISTIC FUN performs only slightly better than the baseline; it optimizes those algorithmic parts that make up only 1% of the overall runtime.

6.3 Performance on various Datasets

The scalability experiments evaluated the performance of HOLISTIC FUN and MUDS on the *uniprot* and the *ionosphere* dataset. To verify the observations that we made on these two datasets, we now evaluate the algorithms on various real-world datasets from the UCI machine learning repository [3]. These UCI datasets have been used in most related work benchmarks and thus allow for comparability of results. We also add the TANE algorithm to this comparison in order to investigate how MUDS performs in comparison to state-of-the-art non-holistic FD discovery. Table 3 lists the execution times of the four profiling algorithms.

As in the scalability experiments, HOLISTIC FUN always performs slightly better than the baseline algorithm showing that a holistic approach should always be preferred over the sequential execution of individual profiling algorithms. The experiment also shows that it strongly depends on the properties of the given input dataset whether MUDS or HOLISTIC FUN is the overall best algorithm: For small numbers of columns and higher numbers of rows, HOLISTIC FUN appears to be the faster algorithm and for higher numbers of columns and small numbers of rows, MUDS performs best. The number of columns, thereby, determines the algorithms’ performance much stronger than the number of rows as the *adult* and the *letter* dataset show, on which MUDS is up to factor 48 faster than HOLISTIC FUN.

When analyzing the algorithms’ performance on the different datasets in detail, we find that some minimal FDs in datasets where MUDS is clearly faster than HOLISTIC FUN have very large left hand sides. The HOLISTIC FUN algorithm, then, must traverse many nodes in the lattice, which is expensive. MUDS, in contrast, utilizes the minimal UCCs for pruning and the depth first search strategy in order to traverse a much smaller part of the lattice. This leads to a clear performance advantage. So in general, the performance of HOLISTIC FUN and MUDS depends on the position of the FDs in the lattice. If the minimal FDs have small left hand sides, HOLISTIC FUN is the better algorithm, be-

Dataset	Col	Row	FDs	basel.	HFUN	MUDS	TANE
iris	5	150	4	.1s	.1s	.1s	.6s
balance	5	625	1	.3s	.1s	.1s	.9s
chess	7	28k	1	2.0s	.9s	1.5s	2.0s
abalone	9	4k	137	1.3s	.6s	1.1s	1.0s
nursery	9	12k	1	2.3s	1.9s	3.1s	3.1s
b-cancer	11	699	46	.8s	.6s	.5s	1.4s

Table 3: Runtime comparison on 11 real world datasets

cause the overhead of finding shadowed FDs in MUDS is unproportionately large. But if there are FDs with large left hand sides in the dataset, MUDS is more efficient. Because the average size of minimal FDs correlates with number of columns, we can choose MUDS or HOLISTIC FUN based on the number of columns. Section 6.5 discusses the difference between HOLISTIC FUN and MUDS in more detail.

When comparing the runtimes of MUDS with the runtimes of TANE, we observe up to 8 times slower runtimes on the *hepatitis* dataset, where many shadowed FDs exist. However, we also see that the holistic algorithm can outperform the non-holistic algorithm by orders of magnitude: It is 8 times faster on the *adult* dataset and 24 times faster on the *letter* dataset. This is possible if MUDS finds favorable pruning conditions, i.e., FDs with large left hand sides. The algorithm can, then, prune much more efficiently than TANE, which makes MUDS also the better FD algorithm here.

6.4 Analysis of MUDS’ phases

Our previous experiments identified MUDS’ last phase, namely the discovery of shadowed FDs, to be its most computationally expensive phase. We now analyze the different phases in more detail. Figure 8 depicts the execution time for each phase of the algorithm. We ran this experiment on 20 columns and 10,000 rows of the *ncvoter* dataset.

Figure 8: Runtime of Muds’ different phases on the *ncvoter* dataset with 10,000 rows and 20 columns

As the measurement show, the computational effort spent on SPIDER and DUCC is almost negligible. The last two phases that detect shadowed FDs, however, are the performance bottleneck of MUDS in this experiment. We observe a 22 times higher execution time than in the previous phases. The *generate shadowed tasks* phase iterates over the already

found FDs and creates tasks for possibly shadowed FDs. Each task immediately checks if the FDs holds. These FD checks consume 78% of the time in this phase. Because the found FDs are not necessarily minimal, MUDS then minimizes the valid FDs in the *minimize shadowed tasks* phase. The FD checks in this phase take 90% of the phase’s time. If the number of discovered shadowed FDs is high, the minimization is very expensive, because minimizing FDs corresponds to a top-down FD discovery that scales exponentially with the number of columns. In both phases, the primary time-consuming operation is the PLI intersect, which is necessary to check whether an FD holds. However, the execution time distribution between the phases of the MUDS algorithm is dataset specific and especially disadvantageous in this experiment. Nevertheless, we observed that the shadowed FD finding part is the most expensive phase of MUDS on all datasets.

6.5 Favorable dataset properties for MUDS

From our previous experiments, we learned that MUDS usually performs best on datasets with ten or more columns. But the number of columns is only one possible indicator for the performance of MUDS over HOLISTIC FUN. In both algorithms, the discovery of FDs is the most expensive part. So to understand the difference between these two approaches better, we have to compare the two FD search strategies in more depth. Depending on the size of these search spaces on the given dataset, one or the other algorithm is superior.

HOLISTIC FUN searches for FDs by starting at the bottom of the lattice and, then, traverses the nodes level-wise until all minimal FDs are found. Thereby, it classifies visited elements into *free sets* and *non-free sets* to prune non-minimal FD candidates. The size of HOLISTIC FUN’s search space is, hence, defined by the height of the lattice levels that hold the minimal FDs; the higher the algorithm has to search, the longer it takes

MUDS first computes all minimal UCCs and, then, searches for FDs in two different search spaces: The first search starts from the minimal UCCs and traverses the lattice in a top-down strategy until all minimal FDs are found (see Section 5.1). All nodes that MUDS traverses in this way are subsets of minimal UCCs and *non-free sets* in the classification of FUN. Because this search space approaches the minimal FDs from the top down, it differs greatly from the search space of HOLISTIC FUN. The second search space of MUDS uses only the columns in $R \setminus A$ for the construction of sub-lattices that are then traversed bottom-up, depth-first (see Section 5.2). This search space overlaps with HOLISTIC FUN’s search space, but it is much smaller depending on the size of $R \setminus A$. Furthermore, MUDS’ depth-first search reaches minimal FDs on high lattice levels much faster than HOLISTIC FUN’s breath-first search.

So MUDS also performs best, if the minimal FDs and minimal UCCs are located on low lattice levels. In comparison to HOLISTIC FUN and any bottom-up, breath-first FD discovery algorithm MUDS performs best when:

1. The minimal UCCs lie close to the minimal FDs in the lattice.
2. The minimal UCCs lie on high lattice levels so that the minimal FDs lie on high lattice levels as well.
3. Many columns participate in at least one minimal UCC, i.e., the column set $R \setminus A$ is small.

Criterion 1 is intuitively clear, because the size of MUDS’ first search space shrinks with the distance of minimal UCCs and FDs. Criterion 2 seems to be a disadvantage for MUDS, because it increases the size of the second search space; but MUDS’ second search space is (a) much smaller than HOLISTIC FUN’s search space and (b) the depth-first search outperforms the breath-first search if this search depth is large. Criterion 3 is a big advantage for MUDS, because its bottom-down search is much faster than the bottom-up search (see Section 6.4).

So now it becomes clear, why MUDS scales better with the number of columns than HOLISTIC FUN: The average distance between minimal UCCs and minimal FDs grows only slightly with the number of columns so that Criterion 1 always holds; the average height and number of both minimal UCCs and minimal FDs grows constantly so that Criterion 2 becomes increasingly advantageous for MUDS; the chances for columns being part of some minimal UCC with some other columns also increases with the number of columns so that the size of column set $R \setminus A$ increases only slightly making Criterion 3 hold.

The number of columns is, however, only an indirect indicator for the performance of MUDS. If the Criteria 1 to 3 do not hold in a particular dataset or if the dataset comprises many rows (see Section 6.1), a lot more columns would be needed to make MUDS faster than HOLISTIC FUN. So we could, instead, use the number and size of minimal UCCs to choose the FD discovery strategy: Because MUDS calculates the minimal UCCs before it starts the FD discovery, one could choose MUDS’ FD discovery part if many, large UCCs have been found or the FUN algorithm if few, small UCCs are found. In practice, however, making the decision based on the number of columns is easier and similarly precise, because the properties “many” and “large” depend on the actual number of rows and columns so that they are non-trivial to define.

7. RELATED WORK

Many data profiling applications, such as data integration and data exploration, need to calculate various metadata at once, but almost all existing algorithms focus on only one task. We already introduced the most important related algorithms for holistic data profiling in Section 2, so we now give a more comprehensive overview on existing IND, UCC, and FD discovery algorithms:

De Marchi et al. [8] presented one of the first algorithms for IND detection. The algorithm constructs an inverted index upon the values of all attributes to check them for inclusions. This technique has been outperformed by the SPIDER algorithm [4] that discards attributes early on. As SPIDER is the currently most efficient algorithm for IND detection, we integrated it in our holistic approaches.

The algorithms for UCC discovery can be separated in two groups: row-based and column-based techniques. Giannella et al. [9] presented a column-based algorithm that generates relevant column combinations to check their uniqueness. An improved version of this algorithm, HCA [1], uses an optimized candidate generation and additional statistical pruning to find UCCs. In both algorithms the check for uniqueness is costly. GORDIAN [16], in contrast, is a row-based UCC discovery algorithm that organizes the data in a prefix tree to check for UCCs. It traverses the tree to determine maximal non-UCCs, which are then used to cal-

culate the minimal UCCs. This is also costly if the number of maximal non-UCCs is large. The currently most efficient UCC algorithm DUCC [10] implements a combination of row-based and column-based techniques: It builds upon efficient data structures and uses UCCs and non-UCCs simultaneously for pruning. Due to the efficiency of DUCC's random walk strategy, we used it in our holistic algorithms.

While TANE [11], proposed by Huhtala et al., is the most popular FD algorithm, it is often outperformed by FUN [14]. TANE and FUN both use partition refinement to identify FDs and apriori-gen to traverse the search space. As FUN additionally incorporates a cardinality inference method that reduces the necessary partition intersect operations, it needs to traverse an overall smaller number of candidates. The CORDS algorithm by Ilyas et al. [12] is capable of identifying various correlations and *soft* FDs. As the algorithm's identification process builds upon sampling techniques, it only approximates the real result.

Although current profiling algorithms focus on one specific profiling task, there are some algorithms that already leverage the knowledge about one type of metadata to draw conclusions about another. The first work in this context was contributed by Beeri and Bernstein [5] who used the defined FDs in a relational database to find additional keys. The algorithms FUN and HCA both use dependencies between FDs and UCCs for pruning. However, they use discovered FDs to derive UCCs, while our algorithm MUDS uses discovered UCCs to derive FDs.

8. CONCLUSION

We investigated the problem of simultaneously discovering three types of metadata: INDs, UCCs, and FDs. By interleaving their calculation, we demonstrated how to share common costs for I/O operations and the traversal of data structures in order to reduce the overall profiling time. Furthermore, we introduced new inter-task pruning and inference rules, in particular rules that derive possible FDs from discovered UCCs. For the analysis of our holistic techniques, we proposed the two algorithms HOLISTIC FUN and MUDS, which jointly discover unary INDs, minimal UCCs, and minimal FDs. HOLISTIC FUN always outperforms the sequential execution of the SPIDER, DUCC, and FUN, the fastest of algorithms for the respective tasks, by avoiding duplicate work. The MUDS algorithm, on the other hand, also facilitates the additional inter-task pruning and inference rules giving it a significant performance advantage on different real world datasets: Our evaluation shows that MUDS is up to 48 times faster than HOLISTIC FUN and the baseline if favorable (and common) pruning conditions (many FDs and UCCs with long left hand sides) are given. On such datasets, MUDS performs even faster than the fastest pure FD algorithm. The number of columns and the size of discovered UCCs can both be used to decide whether MUDS or HOLISTIC FUN should be used.

ABSTRACT

Due to the increase of GPS enabled devices and a lot of location-based services, spatial objects are continuously generated. This paper addresses a problem of monitoring MaxRS (Maximizing Range Sum) in spatial data streams. Given a set of weighted spatial (2-dimensional) objects, this problem is to monitor a location of a given user-specified sized rectangle where the sum of the weights of the objects covered by the rectangle is maximized. Many real life applications obtain a benefit from monitoring MaxRS, e.g., traffic analysis and event detection in urban sensing, but this problem has not yet been addressed so far. Although some algorithms for static objects have been proposed, executing such an algorithm whenever new objects are generated is computationally expensive. These motivate us to develop an efficient algorithm that can monitor MaxRS efficiently. In this paper, we first design a basic algorithm that is based on an index framework and incrementally updates the result. We then enhance the algorithm and show that the enhanced algorithm can deal with error-guaranteed approximation and monitoring top-k MaxRS. Our experimental results confirm the efficiency of our approach.

1. INTRODUCTION

Due to the increase of GPS enabled devices such as smartphones and tablet machines, a lot of location-based services are used in many real life applications. From this fact, spatio-temporal databases have been receiving significant attention recently. Supporting spatial queries is therefore becoming more important, and many studies developed techniques for efficient spatial query processing [13, 15]. These studies can be classified into spatial objects retrieval problems [3, 24] and location finding problems [10, 32, 33]. For example, k NN query processing, which retrieves the k nearest neighbor objects w.r.t. a given query point, is the representative of the spatial objects retrieval problems. In the location finding problems, on the other hand, some queries have been proposed, for example, optimal location queries [10, 33], bichromatic reverse nearest neighbor queries [14, 35], and MaxRS (Maximizing Range Sum) queries [6, 8, 9, 25]. This paper focuses on a kind of MaxRS problem.

Figure 1: An example of a MaxRS query

Motivation. Given a set of weighted spatial (2-dimensional) objects and a user-specified sized rectangle, a MaxRS query finds a location of the rectangle where the sum of the weights of the objects covered by the rectangle is maximized.

EXAMPLE 1.1. Figure 1 shows an example of a MaxRS query. In Figure 1, the rectangle with dashed line, the black points, and the rectangles with solid line show a general monitoring space, spatial objects with weight 1, and user-specified sized rectangles, respectively. The MaxRS query identifies the location of the shaded rectangle as one of the optimal results because it covers the largest number of objects, i.e., the sum of the weights of objects covered by the rectangle is the maximum.

This query is useful because it can automatically find an important place without specifying any query points [8, 9]. In this paper, we address a novel problem of monitoring MaxRS in spatial data streams. In other words, we address a problem of continuous MaxRS query processing over sliding-window. Since a large amount of spatio-temporal objects are *continuously generated* [2, 5], e.g., in the context of location-based service usages, one-time finding an important location does not make sense but continuously monitoring an important location is required. A continuous MaxRS query can achieve this and has the following real life applications.

EXAMPLE 1.2. Consider urban sensing. A system, e.g., base-station, continuously collects spatio-temporal objects, e.g., generated by devices with GPS, in an urban city. Such objects can be represented as $\langle x, y, w \rangle$ where x , y , and w are latitude, longitude, and weight, respectively. If w is communication traffic, a continuous MaxRS query can monitor an area where traffic is concentrated. In this case, the system can notify the users holding mobile devices in the area of warning about communication delay.

Example 1.2 shows that continuous MaxRS queries can help to analyze communication errors and also support decision making, e.g., where to place Wi-Fi access points. We next consider location-

based games in which continuous MaxRS queries are useful for decision making.

EXAMPLE 1.3. *In BotFighters, players try not to be attacked by other players [4], and in Ingress, players try to occupy places. Let w in Example 1.2 represent the strength or level of a given player, and players keep checking the area monitored by a continuous MaxRS query. This can detect an event, e.g., a competition by many and/or high-level players, and support to plan a strategy.*

Other examples include mobile sensor networks [27] that a base-station continuously collects sensor readings. By employing continuous MaxRS queries, the base-station may be able to detect sensor failures and over-concentration of mobile sensor nodes.

Technical challenge and overview. Some techniques for exact MaxRS query processing on static objects have been developed in the past. [12, 18] proposed in-memory algorithms while [8, 9] proposed an external-memory algorithm. The computation (I/O) complexity of the in-memory (external-memory) algorithm is shown to be optimal. These algorithms however focus on *one-time* computation, so they are not efficient for continuous MaxRS queries. This is because computing the result from scratch whenever new objects are generated is obviously computationally expensive, meaning that an approach which can incrementally update the result is required.

In this paper, we first propose a basic algorithm that exploits a graph in grid index, namely G2. G2 integrates graph and grid structures, thus its storage cost is $O(|V| + |E|)$, where V corresponds to a set of objects on a given sliding-window and E is a set of edges. (The details are described in Section 4). One of the properties of G2 is that no overhead incurs when objects expire. We then enhance both the basic algorithm and G2, and propose aggregate G2, aG2, and a branch-and-bound algorithm that exploits aG2. This algorithm eliminates unnecessary update computation as much as possible and accelerates the query processing efficiency.

Interestingly, the branch-and-bound algorithm can deal with error-guaranteed approximation. Let w^* and ϵ respectively be the maximum range sum and a user-tolerance error rate. Also, let w be the weight of the area monitored by the algorithm, and we can guarantee that $w \geq (1 - \epsilon)w^*$. We show that the relationship between query processing efficiency and ϵ is trade-off but the practical error rate is much less than ϵ . In addition to the approximation, we consider a problem of monitoring top- k MaxRS. For example, Examples 1.2 and 1.3 may require not only a single area but k (e.g., 5) areas with the largest range sum. This requirement is satisfied by a simple modification of the branch-and-bound algorithm.

Contributions and organization. We summarize our contributions as follows.

- We address a novel problem of continuous MaxRS query processing in spatial data streams (Section 2). To the best of our knowledge, we are the first to investigate this problem.
- We design a basic algorithm for a continuous MaxRS query (Section 4). This algorithm incrementally updates the result by exploiting an efficient index framework.
- We enhance the basic algorithm and propose a more efficient index and branch-and-bound algorithm (Section 5). This algorithm prunes unnecessary computation and accelerates the computation efficiency.
- We show that the branch-and-bound algorithm can deal with error-guaranteed approximation and efficient continuous top- k MaxRS query processing (Section 6).

- We conduct extensive experiments using both synthetic and real datasets that confirm the efficiency of our approach (Section 7).

In addition to the above contents, we review some related literatures in Section 3, and Section 8 concludes this paper.

2. PRELIMINARY

We are given a set of spatial stream objects in a general monitoring space, as shown in Figure 1. A spatial object o_i is represented by $o_i = \langle x, y, w \rangle$ where i is its identifier, $\langle x, y \rangle$ shows the location that o_i is generated, and w is a non-negative value (weight), i.e., $o_i.w \in \mathbb{R}^+$. We assume a spatial stream environment, thus consider a sliding-window model [1] because it is usual that many applications are interested only in recent objects. Count- and time-based sliding-window models are widely accepted. The count-based sliding-window considers the most recent n objects, and in this model, m new objects generations lead to the expirations of the m oldest objects. The time-based sliding-window, on the other hand, considers the objects generated within the last T time-units. Selection of a suitable sliding-window model depends on applications, and our algorithms can deal with both the models. So, without loss of generality, we assume the count-based sliding-window in this paper. Let O be the set of the most recent n objects, and O residents in-memory because real-time continuous query processing generally requires main memory computation [4, 17].

Let P be an infinite set of points in the general monitoring space. Given a user-specified sized rectangle r , the weight of a point $p \in P$, $p.w$, is defined by

$$p.w = \sum o_i.w,$$

where $o_i \in O$ is covered by r centered at p . We are now ready to formally define the monitoring MaxRS problem.

DEFINITION 1 (MONITORING MAXRS PROBLEM). *Given a set of objects on a sliding-window O , an infinite set of points in the general monitoring space, and a user-specified sized rectangle r , the goal of the monitoring MaxRS problem is to continuously monitor a location $p^* \in P$ that satisfies.*

$$p^* = \operatorname{argmax}_{p \in P} p.w.$$

It is infeasible to find and monitor p^* from such infinite points, but as the literatures [8, 9, 25] introduce, MaxRS problems can be solved by transformation to an alternative problem. Given a user-specified sized rectangle r , let r_i be the weighted rectangle of the same size of r centered at $\langle o_i.x, o_i.y \rangle$ ($o_i \in O$ and $r_i.w = o_i.w$). Consider $o_i, o_j \in O$, and if r_i overlaps with r_j , it is not difficult to see that the weight of the overlapped space s is $s.w = r_i.w + r_j.w$. We formally define this *space weight*.

DEFINITION 2 (SPACE WEIGHT [8]). *Given O , we have a set of rectangles each of which is centered at the location of the corresponding object. The weight of a space s is the sum of the weights of the rectangles covering s .*

Then the alternative problem is to find s with the maximum weight denoted by s^* . Interestingly but not surprisingly, p^* exists in s^* , that is, any points in s^* can be p^* .

EXAMPLE 2.1. *Figure 2 shows the alternative problem of Figure 1. The center of each rectangle is at the corresponding object. Note that the size of each rectangle is the user-specified size. Recall that the weight of each object is 1, and the shaded overlapped space has*

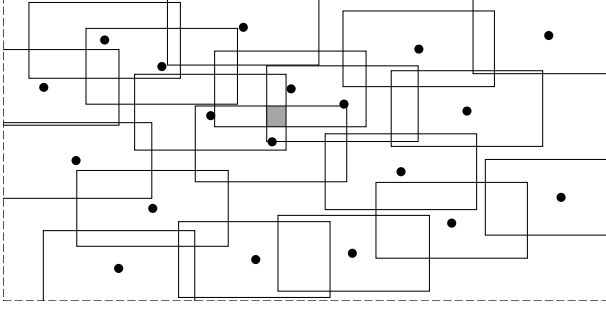

Figure 2: An example of the alternative problem of Figure 1

the maximum weight. We know that the weights of other overlapped spaces are less than 4. The center of the shaded rectangle in Figure 1 exists in the shaded space.

Therefore, monitoring s^* is equivalent to monitoring p^* . We here define continuous MaxRS queries that solve the monitoring MaxRS problem.

DEFINITION 3 (CONTINUOUS MAXRS QUERY). Given a set of objects on a sliding-window O and a user-specified sized rectangle r , each weighted object is converted to a weighted rectangle centered at the location of the object. A continuous MaxRS query monitors s^* that satisfies

$$s^* = \operatorname{argmax}_{s \in S} s.w, \quad (1)$$

where S is the set of overlapped spaces.

We also consider a problem of monitoring top-k MaxRS to support the applications that require not only a single space but also k spaces with the maximum weight. The definition of monitoring top-k MaxRS problem is given by extending Definition 1, thus we formally define continuous top-k MaxRS queries below.

DEFINITION 4 (CONTINUOUS TOP-K MAXRS QUERY). Given a set of objects on a sliding-window O and a user-specified sized rectangle r , each weighted object is converted to a weighted rectangle centered at the location of the object. A continuous top-k MaxRS query monitors the set S^* that satisfies $|S^*| = k$ and $\forall s \in S^* \text{ and } \exists s' \in S \setminus S^*, s.w \geq s'.w$ where S is the set of overlapped spaces, and ties are arbitrarily broken.

Since applications that execute continuous queries basically require real-time monitoring [3, 4, 17], algorithms that process such queries have to update query results efficiently. Our objective of this paper is therefore to minimize computation time to update s^* , which is incurred by generations and expirations of objects. Table 1 summarizes the symbols frequently used in this paper.

3. RELATED WORK

As introduced in Section 1, many spatial queries have been developed. This section reviews related works of the monitoring MaxRS problem. In particular, we introduce spatial preference queries and facility location queries in which MaxRS queries are categorized. We then review the existing studies of MaxRS query processing.

Before introducing the above queries, we should make it clear that MaxRS queries are different from range aggregation queries. The goal of range aggregation queries is to return the aggregate result (e.g., values and points) from (i) the set of points in a given rectangle with fixed location [19, 21, 23] or (ii) the set of values in a given interval [26]. On the other hand, the goal of MaxRS queries is

Table 1: Overview of symbols

Symbol	Description
o_i	The weighted spatial object with identifier i
m	The number of objects generated at the same time
s^*	The space with the maximum weight
r_i	The weighted rectangle centered at the location of o_i
$r_i.E$	The set of edges held by r_i
$N(r_i)$	The set of neighboring vertices (rectangles) of r_i
s_i	The space with the maximum weight covered by r_i
$c_{i,j}$	The cell with identifier (i, j)
$G_{i,j}$	The graph maintained by $c_{i,j}$
$V_{i,j}$	The set of vertices (rectangles) of $G_{i,j}$
$c_{i,j}.w$	The upper-bound weight of $c_{i,j}$

to find a location from an infinite set of points. In the same sense, continuous spatial queries [15, 16, 17] that monitor not locations but objects are different from our problem.

Spatial preference queries. Spatial preference query processing problem is one of location selection problems. Given a 2-dimensional point p and a distance constraint d , a top-k spatial preference query [22, 29] determines the score of p by the sum of the weights of the feature objects existing within d from p . [28] studies a problem of finding top- t most influential sites. The influential score of a given site is defined as the sum of weights of its reverse nearest neighbor objects. In the above queries, the scores of the target points are defined by a kind of range sum function. However, the locations of the target points are already known, which is different from our problem.

Facility location queries. The objective of this problem is to find an optimal location w.r.t. a given condition. It is often the case that a set of customers (or clients) with weights and a set of facilities are given [11]. Then a facility location query retrieves a facility that maximizes the total weight of its reverse (k) nearest neighbor customers [35]. [10] proposed optimal location queries, and the extension version of the optimal location queries, min-dist optimal location queries, has been studied in [20, 32]. Such optimal location queries have also been studied in road networks [7].

The monitoring MaxRS problem is also one of the facility location problems. We are interested in continuously monitoring a location that maximizes the total weight of objects covered by a user-specified sized rectangle. As introduced in Section 1, this is useful in monitoring applications in spatial data streams. The main difference between MaxRS and the above queries is their categories: *monotonic* (e.g., MaxRS queries) and *bichromatic* (e.g., optimal location queries).

MaxRS queries. To the best of our knowledge, the existing works of MaxRS problems and the variants are [6, 8, 9, 12, 18, 25]. An external-memory algorithm for exact MaxRS queries has been proposed in [8, 9], while [25] proposed a randomized sampling algorithm that bounds the error with high probability. That is, given a tolerance error ϵ , the approximate algorithm returns a space with the weight w that satisfies $w \geq (1 - \epsilon)w^*$ with probability $1 - \frac{1}{n}$. (w^* is the weight of the optimal result and n is the number of objects.) Rotating MaxRS queries have been proposed in [6]. This literature assumes that a given rectangle is rotatable, but we do not assume this case and assume the usual case, as well as [8, 9, 12, 18, 25].

We now focus on the in-memory algorithms [12, 18] because we also consider an in-memory algorithm for continuous MaxRS queries. It is notable that the algorithm in [18] solves a max-

Figure 3: An example of processing a plane-sweep algorithm

enclosing rectangle problem, to which the MaxRS problem can be converted, based on well-known *plane-sweep* strategy, and actually the external-memory and the approximate algorithms [8, 25] also employ this strategy. (The algorithm proposed in [12] also employs the same strategy and the computation cost is the same as [18].) The plane-sweep algorithm [18] employs a horizontal line, and given a set of rectangles, this line is swept from bottom to top of the rectangles while counting the weights of intersecting intervals on the sweeping line. Figure 3 shows an instance when sweeping the dashed line. Let the weight of each rectangle in Figure 3 be 1, and we can see that the weights of intervals AB, BC, and CD are 1, 2, and 3, respectively. In the plane-sweep algorithm, when a sweeping line reaches the bottom edge of a rectangle, a newly generated interval is inserted into a binary-tree, while when reaching the top of the rectangle, the expired interval is deleted from the binary-tree. During these procedures, the counts of intervals are also updated. This algorithm returns the interval with the maximum weight, and the complexity of this algorithm is $\mathcal{O}(n \log n)$ [18], where n is the number of objects (rectangles). This is because the algorithm executes $2n$ binary-tree updates (n insertions and n deletions) that take $\mathcal{O}(\log n)$ time. (This algorithm also can return a set of k intervals with the maximum weight without sacrificing its computation efficiency.)

The above algorithm is shown to be an optimal solution for the MaxRS problem on *static objects*. However, it is inefficient to compute s^* from scratch by this algorithm even in the case where the number of newly generated objects is not large, which is shown by our experimental results. From the next section, we describe our solutions that efficiently update and monitor the result over stream data.

4. BASIC SOLUTION

The generations and the expirations of objects lead to additions and eliminations of overlapped spaces. This suggests that S in Equation (1) is dynamic, in other words, the ranking of range sum is dynamic, thereby efficient s^* monitoring is not trivial. In spite of this nature, our index framework enables to design a simple but efficient algorithm.

4.1 G2: Graph in Grid Index

We first present our index framework Graph in Grid index (or G2). Recall that our objective is to achieve real-time monitoring of MaxRS in a stream environment, meaning that unnecessary computations have to be avoided. A dynamic graph, where a vertex is a rectangle and an edge shows the overlap between given two vertices, realizes this. If the weight of each vertex (rectangle) is 1, we can see that s^* is a part of the vertex with the largest number of edges. To monitor s^* with using the dynamic graph, the basic operation that we have to do is just to check the updated parts of the dynamic graph. This is because only the updated parts may affect s^* . Motivated by this observation, we develop G2.

As described, the first idea is to maintain n rectangles on a sliding-window by a graph. Vertices of the graph are the rectangles, and if two rectangles overlap each other, there is an edge between them.

Figure 4: The graph constructed from the rectangles in Figure 3

Table 2: Edge and neighbor sets of the vertices of the graph in Figure 4

Vertex r_i	Edge $r_i.E$	Neighbor set $N(r_i)$
r_1	$(r_1, r_2), (r_1, r_3)$	$\{r_2, r_3\}$
r_2	(r_2, r_3)	$\{r_3\}$
r_3	(r_3, r_4)	$\{r_4\}$
r_4	(r_4, r_5)	$\{r_5\}$
r_5	(r_5, r_6)	$\{r_6\}$
r_6	\emptyset	\emptyset

We define our graph and provide a concrete example below.

DEFINITION 5 (GRAPH G). $G = (V, E)$ is a dynamic graph. V is a set of rectangles of a given size on a sliding-window, and E is a set of direct edges. Given two vertices $r_i, r_j \in V$ overlapping each other, where r_i was generated earlier than r_j , there is a direct edge between them, (r_i, r_j) , and this edge is held by the vertex (rectangle) that was generated earlier than the other, i.e., r_i . (Ties are broken by identifiers.)

EXAMPLE 4.1. We construct a graph G from the set of rectangles in Figure 3, and Figure 4 shows G . Assume that the rectangles are generated in order of identifiers. Since r_2 overlaps with r_1 , there is (r_1, r_2) that represents a direct edge from r_1 to r_2 . r_1 maintains the edges (r_1, r_2) and (r_1, r_3) .

When context is clear, we use vertices and rectangles interchangeably since they are the same, as Definition 5 describes. We denote $r_i.E$ the set of edges held by the vertex $r_i \in V$. The set of neighbors of a vertex $r_i \in V$ is also denoted by $N(r_i) = \{r_j \mid \exists (r_i, r_j) \in r_i.E\}$. Table 2 shows an example that uses Figure 4 in terms of $r.E$ and $N(r)$. Then we obtain the spaces on r_i covered by the rectangles in $N(r_i)$. r_i maintains s_i , the space with the maximum weight among the spaces. That is, s_i is definitely the subspace on r_i , which provides the following property.

PROPERTY 1. Given $r_i, r_j \in V$, we have that $s_i \neq s_j$.

The proof is straightforward since $\nexists r_i \in N(r_j)$ if $\exists r_j \in N(r_i)$. How to obtain s_i is explained later, but it is not difficult to see the following property.

PROPERTY 2. Let S_G be the set of s_i maintained by r_i on a sliding-window, we have that

$$s^* = \operatorname{argmax}_{s_i \in S_G} s_i.w. \quad (2)$$

Furthermore, even if some vertices (rectangles) expire, other vertices need no maintenances, because the corresponding edges are held by older vertices.

PROPERTY 3. Given $r_i \in V$, and when the older vertices than r_i expire, s_i does not change.

We next have to consider the case where m new rectangles (objects) are generated. Due to the graph structure, we need to check whether the m rectangles overlap with the existing rectangles. It is obvious that simple computation takes $\mathcal{O}(mn)$ time. To alleviate this, we employ a grid structure like the one shown in Figure 5,

Figure 5: An example of G2

which is the second idea. When dataset updates frequently occur, grid structure is more suitable than complex structures like R-tree and Quad-tree [4]. Each cell in the grid is assigned an identifier and its size is fixed, as shown in Figure 5. Note that each cell $c_{i,j}$ maintains the graph constructed by the mapped rectangles, denoted by $G_{i,j} = (V_{i,j}, E_{i,j})$. Therefore, Definition 5 is rewritten as follows.

DEFINITION 6 (GRAPH $G_{i,j}$). $G_{i,j} = (V_{i,j}, E_{i,j})$ is a dynamic graph maintained by $c_{i,j}$ of a grid. $V_{i,j}$ is a set of given sized rectangles that are mapped to $c_{i,j}$ and on a sliding-window, and $E_{i,j}$ is a set of direct edges. The condition of direct edges follows Definition 5.

For example, Figure 5 illustrates an example of a G2 and $G_{3,0}$. When m new rectangles are generated, we map them to the cells with which they overlap. (So, a new rectangle may be mapped to multiple cells.) We then update the graphs in the cells where new objects are mapped.

Complexities. The time complexity of the rectangle mapping is $\mathcal{O}(m)$. Let c' and m' respectively be the number of cells where new objects are mapped and the average number of new objects mapped to the cells. Also, let n' be the average number of vertices in the cells where new objects are mapped, and the time complexity of the graph update is $\mathcal{O}(c'm'n')$. In practice, we have that $n' \ll n$. We next consider storage cost. Let V be the set of all vertices in the grid, then we know that $|V| = \sum |V_{i,j}|$. Similarly, $|E| = \sum |E_{i,j}|$, where E is the set of all edges in the grid. Recall that each vertex r_i maintains s_i and its storage cost is $\mathcal{O}(|V|)$. We can therefore conclude that the storage cost of G2 is $\mathcal{O}(|V| + |E|)$.

4.2 Monitoring Algorithm with G2

We design an online monitoring algorithm using G2, and Algorithm 1 illustrates the high level algorithm.

Algorithm description. Consider an instance when m new rectangles are generated and the m oldest rectangles expire. As described in Section 4.1, we first update G2 (lines 1–3). Lines 4–6 are designed based on the following idea. Given the set S of the spaces each of which (i.e., s_i) is maintained by $r_i \in V$, we know that s_i has to be correct due to Equation (2). In addition, if a new edge is inserted to $r_i.E$, s_i may change because $N(r_i)$ varies. We therefore need to compute s_i if $r_i.E$ is updated. The plane-sweep algorithm is an optimal solution to find the space with the maximum weight covered by the given rectangles [12]. Hence, we employ the plane-sweep algorithm to compute s_i (line 6). Note that the input of this plane-sweep algorithm is *only* $N(r_i) \cup \{r_i\}$. To summarize, for $\forall r_i \in V$, where $r_i.E$ has new edges and V is the vertex set maintained by a given cell c of G2, Algorithm 1 executes the plane-sweep algorithm locally, denoted by Local-Plane-Sweep(\cdot) (lines 4–6). After that, we can correctly monitor s^* .

Algorithm 1: Monitoring algorithm using G2

```

1 Mapping( $R$ ) //  $R$  is the set of new rectangles
2  $C' \leftarrow$  the set of the cells where new objects are mapped
3 G2-Update( $C'$ ) // rectangle overlap computation
4 for  $\forall c \in C'$  do
5   for  $\forall r_i \in c.V$  where  $r$  has new edges do
6      $s_i \leftarrow$  Local-Plane-Sweep( $N(r_i) \cup \{r_i\}$ )
7  $s^* \leftarrow \operatorname{argmax}_{s_i \in S} s_i.w$ 
8 return  $s^*$ 

```

Recall that given a set of rectangles, the plane-sweep algorithm sweeps a horizontal line from the bottom to the top among the rectangles. To obtain s_i , however, we only need to sweep the horizontal line from the bottom to the top of r_i . Local-Plane-Sweep(\cdot) in Algorithm 1 (line 6) is optimized to do so. Although the time complexity does not vary, the practical execution time is reduced.

The following simple example highlights the efficiency of our incremental approach.

EXAMPLE 4.2. Assume that the graph in Figure 4 is the graph maintained by one of the cells in Figure 5. Assume further that $m = 1$ and r_6 is the new rectangle mapped to the cell. Algorithm 1 checks the vertices overlapping with r_6 , and in this case, (r_5, r_6) is inserted to $r_5.E$. Algorithm 1 next executes Local-Plane-Sweep($\{r_5, r_6\}$) and obtains s_5 . If $s_5.w > s^*.w$, s^* is replaced by s_5 .

Time complexity. As discussed before, lines 1–3 take $\mathcal{O}(c'm'n')$ time. Let v be the number of vertices to which new edges are inserted. Also, let e be the average number of edges of the above vertices, then lines 4–6 take $\mathcal{O}(ve \log e)$ time since Local-Plane-Sweep(\cdot) for a vertex takes $\mathcal{O}(e \log e)$ time. Therefore, when m new objects are generated, Algorithm 1 takes $\mathcal{O}(c'm'n' + ve \log e)$ time.

5. ENHANCED SOLUTION

Algorithm 1 can identify *where to update* and compute s_i maintained by r_i efficiently since $N(r_i)$ is easily obtained by the graph representation. In fact, however, the most time consuming operation in Algorithm 1 is Local-Plane-Sweep(\cdot) (line 6). Algorithm 1 executes Local-Plane-Sweep(\cdot) whenever $r_i.E$ is updated, thus it is intuitively seen that the approach degrades the performance in the case where the number of $r_i.E$ updates is large. We observe the following usual cases that motivate to enhance G2.

1. The $r_i.E$ update increases $s_i.w$ but it is less than $s^*.w$.
2. The $r_i.E$ update does not increase $s_i.w$.

To consider a more concrete situation, we give Example 5.1, and Table 3 shows the weights of each vertex r_i and s_i of the graph in Figure 4.

Table 3: Weights of vertex r_i and s_i of the graph in Figure 4

Vertex r_i	$r_i.w$	$s_i.w$
r_1	10	55
r_2	30	45
r_3	15	40
r_4	25	45
r_5	20	25
r_6	5	5

(a) An instance when the rectangle overlap computation has been executed.

(b) An instance when new rectangles are mapped to $c_{3,0}$.

(c) An instance when the rectangle overlap computation between $V_{3,0}$ and $R_{3,0}$ in Figure 6(b) has been executed.

Figure 6: An example of $G_{3,0}$ (followed by Figure 5) and $R_{3,0}$ of $c_{3,0}$ in an aG2 and its dynamic update where the weight of each vertex is 1.

EXAMPLE 5.1. Assume the same situation as Example 4.2 and $s^* = s_1$. Before (r_5, r_6) is inserted to $r_5.E$, $s_5.w = 20$, and after the insertion, we obtain $s_5.w = 25$. However, it is obvious that the edge (r_5, r_6) insertion to $r_5.E$ does not affect s^* , which corresponds to the case 1. In addition, even if r_6 overlaps with r_2 and does not overlap with r_3 , s_2 keeps the same and does not become s^* . This corresponds to the case 2.

The observation in Example 5.1 suggests that we may not have to compute s_i even when $r_i.E$ is updated. Therefore, by enhancing G2, we aim at eliminating such unnecessary computation and improving query processing efficiency. The enhanced solution achieves this by an upper-bounding technique.

5.1 Aggregate G2

It has been shown in the past that data structures considering aggregate results work well for query processing which deal with aggregate functions such as `sum` and `count` [30]. The monitoring MaxRS problem considers `sum` function, then we know that G2 can be extended to deal with aggregate values like aR-tree [19].

We propose aG2 (aggregate G2), which is essentially G2. The main difference between G2 and aG2 is that aG2 employs *upper-bound weights*. Given a graph in an aG2, each vertex r_i of the graph maintains $s_i.\bar{w}$, which is the upper-bound weight of s_i . How to compute $s_i.\bar{w}$ depends on algorithms, so we briefly introduce our approach to compute $s_i.\bar{w}$ here (the detail is described in Section 5.2). Given the graph $G_{i,j} = (V_{i,j}, E_{i,j})$ maintained by a cell $c_{i,j}$ in an aG2, we have a vertex $r_{i'} \in V_{i,j}$ and $s_{i'}$. Consider rectangles $r_{j'}$ where $(r_{i'}, r_{j'})$ is newly inserted to $r_{i'}.E$, $s_{i'}.\bar{w}$ is computed by the following Equation.

$$s_{i'}.\bar{w} = s_{i'}.w + \sum r_{j'}.w \quad (3)$$

Not only the vertices but also the cells in aG2 maintain upper-bound weights. Before we introduce the upper-bound weight maintained by $c_{i,j}$, we have to note that in aG2, $c_{i,j}$ maintains

- $G_{i,j}$: the graph defined by Definition 6, and
- $R_{i,j}$: a set of rectangles that have been mapped to $c_{i,j}$ but have not yet been checked whether they overlap with vertices in $V_{i,j}$ or not (denoted by rectangle overlap computation).

The new rectangles mapped to $c_{i,j}$ are initially maintained in $R_{i,j}$. When we execute the rectangle overlap computation, the rectangles in $R_{i,j}$ are moved to $V_{i,j}$. Now we introduce how to compute

$c_{i,j}.w$, i.e., the upper-bound weight maintained by $c_{i,j}$. Basically, $c_{i,j}.w$ is set as follows.

$$c_{i,j}.w = \max_{s_{i'} \in S_{i,j}} s_{i'}.\bar{w}, \quad (4)$$

where $S_{i,j}$ is the set of $s_{i'}$ maintained by $r_{i'} \in V_{i,j}$. Given a set of new rectangles r' that are mapped to $c_{i,j}$, $c_{i,j}.w$ is updated by the following equation.

$$c_{i,j}.w \leftarrow c_{i,j}.w + \sum r'.w \quad (5)$$

We give a simple example of how to dynamically update upper-bound weights below.

EXAMPLE 5.2. Figure 6 shows an example of $G_{3,0}$ and $R_{3,0}$ where $c_{3,0}$ follows Figure 5. We first assume the situation of Figure 6(a), and note that the value shown next to each vertex is the upper-bound weight. Then we see that $c_{3,0}.w = 4$, which is the maximum value among the upper-bound weights of $V_{3,0}$. Next we assume that three new rectangles are mapped to $c_{3,0}$, which are maintained in $R_{3,0}$, as shown in Figure 6(b). From Equation (5), $c_{3,0}.w$ is updated to 7. We finally assume Figure 6(c), where the three rectangles in $R_{3,0}$ have been checked whether they overlap with the vertices (rectangles) in $V_{3,0}$ or not. Note that the upper-bound weight maintained by each vertex is updated and $c_{3,0}.w$ is also updated to 4 as the result of the rectangle overlap computation.

From Equations (3)–(5), we have the following property.

PROPERTY 4. $c_{i,j}.w \geq s_{i'}.\bar{w} \geq s_{i'}.w$ for $\forall r_{i'} \in V_{i,j}$.

Because of generations and expirations of rectangles, those upper-bound weights may vary dynamically, but our branch-and-bound algorithm (introduced later) dynamically updates the upper-bound weights so that Property 4 is kept. At the same time, this property provides the correctness of our branch-and-bound algorithm.

As well as G2, we discuss about the storage cost of an aG2 below.

PROPERTY 5. An aG2 has the same storage cost as a G2, i.e., $\mathcal{O}(|V| + |E|)$ where V and E are respectively the sets of all the vertices and the edges in the (a)G2.

PROOF. To prove Property 5, we have to discuss about the storage costs of vertices, edges, and upper-bound weights. Let $n_{i,j}$ and $n'_{i,j}$ be the size of $V_{i,j}$ in G2 and aG2, respectively. Because $V_{i,j} \cap R_{i,j} = \emptyset$ in aG2, we have that $n_{i,j} = n'_{i,j} + |R_{i,j}|$, thereby $|V| = \sum (n'_{i,j} + |R_{i,j}|)$. The number of edges in aG2 may be less than that of G2 but it takes $\mathcal{O}(E)$ cost. Let V' be the set of $V_{i,j}$ of

aG2, and $|V| > |V'| = \sum n'_{i,j}$. The storage cost of upper-bound weights maintained by vertices is $\mathcal{O}(|V'|)$. Let C be the set of cells of an aG2, and the storage cost of upper-bound weights maintained by the cells is $\mathcal{O}(|C|)$. We know that $|C| \ll |V'|$ in practice. Therefore we can complete the proof. \square

5.2 Branch-and-Bound Algorithm

As described in Section 5.1, each cell and vertex in an aG2 maintain the upper-bound weights. This enables us to process a continuous MaxRS query while pruning unnecessary computations. Specifically, we can obtain two pruning rules, which can reduce the number of executions of LocalPlaneSweep(\cdot). Assume an instance when m new rectangles are generated, the upper-bound weight of each cell is obtained by Equation (5). Given s^* , we first obtain the following pruning rule.

PRUNING RULE 1. *Given a cell $c_{i,j}$ in the aG2, and if $c_{i,j}.w < s^*.w$, all the vertices in $V_{i,j}$ do not have s^* . Therefore we do not need to compute the exact $s_{i'}$ of $r_{i'}$ in $V_{i,j}$.*

The above case efficiently prunes the computation of the exact $s_{i'}$. However, we are likely to hold the case where $c_{i,j}.w \geq s^*.w$, since $c_{i,j}.w$ is the maximum value among the set of the upper-bounds maintained by vertices in $G_{i,j}$ or more (See Equation(5)). In this case, we focus on each vertex in $V_{i,j}$, and then apply the next pruning rule.

PRUNING RULE 2. *Given a cell $c_{i,j}$ in the aG2, and we assume that $c_{i,j}.w \geq s^*.w$. Given a vertex $r_{i'}$ in $V_{i,j}$, if $s_{i'}.w < s^*.w$, $r_{i'}$ does not have s^* , thus we do not need to compute the exact $s_{i'}$.*

From the above pruning rules, we can focus only on cells and vertices with non-zero probability to have s^* . Note that the above pruning rules assume that s^* is given, although s^* might expire. If s^* expires, we first obtain a temporal s^* , and the temporal s^* is retrieved from the cell c that satisfies

$$c = \operatorname{argmax}_{c_{i,j} \in C} c_{i,j}.w, \quad (6)$$

where C is the set of cells in the aG2. To keep the efficiency of the pruning rules, the weight maintained by the temporal s^* should be large as much as possible. It is intuitive that a cell with large upper-bound weight probably has the space with large weight, thereby we employ this heuristic. From the above discussion, we design a branch-and-bound algorithm, which efficiently updates s^* and is illustrated in Algorithm 2.

Algorithm description. Consider an instance when m new rectangles are generated and the m oldest rectangles expire. We first map the newly generated rectangles to the corresponding cells $c_{i,j}$ while updating the upper-bound weight $c_{i,j}.w$ and $R_{i,j}$ (lines 1–5). Next, we update (or find a temporal) s^* to enhance the pruning efficiency (line 6–10). Let c is the cell holding s^* (if s^* expires, we retrieve c that satisfies Equation (6)), we execute $\text{OverlapComputation}(c)$ (line 9), which is illustrated in Algorithm 3. $\text{OverlapComputation}(c)$ updates the graph in c and $c.w$. More specifically, we check whether rectangles in R of the cell c overlap with the rectangles (vertices) in V , and if overlap, new edges are inserted while updating the upper-bound weights maintained by the vertices and c (lines 3–8 in Algorithm 3). After that, $\text{ExactWeightComputation}(s^*, c)$ is executed (line 10 in Algorithm 2), which is illustrated in Algorithm 4. In $\text{ExactWeightComputation}(s^*, c)$, we apply Pruning rule 2 to each vertex r_i . If $s_i.w > s^*.w$, we execute $\text{LocalPlaneSweep}(\cdot)$ for r_i , and update s^* if necessary (lines 6–10 in Algorithm 4). Also, $c.w$ is kept so that it satisfies Equation (4). From the above procedures, we obtain the updated (or temporal) s^* , and then a branch-

Algorithm 2: Branch-and-bound algorithm using aG2

```

1  $R_{\text{new}} \leftarrow$  the set of newly generated rectangles
2 for  $\forall r \in R_{\text{new}}$  do
3   if  $r$  is mapped to  $c_{i,j}$  then
4      $c_{i,j}.w \leftarrow c_{i,j}.w + r.w$ 
5      $R_{i,j} \leftarrow R_{i,j} \cup \{r\}$ 
6  $c \leftarrow \{c_{i,j} \mid s^* \text{ is in } c_{i,j}\}$ 
7 if  $s^*$  expired ( $c = \emptyset$ ) then
8    $c \leftarrow \operatorname{argmax}_{c_{i,j} \in C} c_{i,j}.w$  //  $C$  is the set of cells in aG2
9  $\text{OverlapComputation}(c)$ 
10  $s^* \leftarrow \text{ExactWeightComputation}(s^*, c)$

10    $c_{i,j}.w \leftarrow r'.w$ 
11  $s'.w \leftarrow r'.w$ 
12  $V_{i,j} \leftarrow V_{i,j} \cup \{r'\}$ 
13  $R_{i,j} \leftarrow R_{i,j} \setminus \{r'\}$ 

```

and-bound approach is employed (lines 11–15 in Algorithm 2) to guarantee the correct s^* .

Given a cell $c_{i,j}$, we first apply Pruning rule 1, and if $c_{i,j}.w > s^*.w$, we update (i.e., decrease) $c_{i,j}.w$ by $\text{OverlapComputation}(c_{i,j})$ (lines 12–13). Again we apply Pruning rule 1 to $c_{i,j}$, and if $c_{i,j}.w > s^*.w$ again, $\text{ExactWeightComputation}(s^*, c_{i,j})$, which we explained above, is executed. In the case where we compute the exact $s_{i'}$ maintained by $r_{i'}$ in $V_{i,j}$, in $\text{ExactWeightComputation}(s^*, c_{i,j})$, and $s_{i'}.w > s^*.w$, s^* is updated (line 10 in Algorithm 4). These operations are executed for $\forall c_{i,j} \in C \setminus \{c\}$, and after that, we can keep monitoring the correct s^* .

Time complexity. $\text{OverlapComputation}(c_{i,j})$ takes $\mathcal{O}(|V_{i,j}| |R_{i,j}|)$. Let C' be the set of the cells that $\text{OverlapComputation}(\cdot)$ is executed, and the amortized time to compute the rectangle overlapping is $\mathcal{O}(|C'| |V_{i,j}| |R_{i,j}|)$. Let v' be the number of the vertices that $\text{LocalPlaneSweep}(\cdot)$ is executed. Also let e' be the average number of edges of the above vertices, and the total cost of $\text{ExactWeightComputation}(\cdot, \cdot)$ is $\mathcal{O}(v' e' \log e')$. When m new objects are generated, Algorithm 2 takes $\mathcal{O}(|C'| |V_{i,j}| |R_{i,j}| + v' e' \log e')$ (amortized) time. Recall the time complexity of Algorithm 1, and note that $|C'| |V_{i,j}| |R_{i,j}| \leq c' m' n'$ and $v' e' \log e' < v e \log e$.

Correctness. The correctness of Algorithm 2 is proven by Property 4. In Algorithms 2–4, we define the condition that we cannot prune $\text{OverlapComputation}(\cdot)$ and $\text{ExactWeightComputation}(\cdot, \cdot)$ as “ $>$ ” instead of “ \geq ,” e.g., line 12 of Algorithm 2. This is because

Algorithm 4: ExactWeightComputation($s^*, c_{i,j}$)

Input: $s^*, c_{i,j}$ // $c_{i,j}$ is a cell in aG2

```

1  $c_{i,j}.w \leftarrow 0$ 
2 for  $\forall r_{i'} \in V_{i,j}$  do
3    $\rho \leftarrow 0$ 
4   if  $s^* \neq \emptyset$  then
5      $\rho \leftarrow s^*.w$ 
6   if  $s_{i'}.w > \rho$  then
7      $s_{i'} \leftarrow \text{Local-Plane-Sweep}(N(r_{i'} \cup \{r_{i'}\}))$ 
8      $s_{i'}.w \leftarrow s_{i'}.w$ 
9     if  $s_{i'}.w > s^*.w$  then
10        $s^* \leftarrow s_{i'}$ 
11   if  $c_{i,j}.w < s_{i'}.w$  then
12      $c_{i,j}.w \leftarrow s_{i'}.w$ 
13 return  $s^*$ 

```

we monitor one of the spaces with the maximum weight, thus if $s^*.w = c_{i,j}.w$ for example, we keep monitoring s^* , and this does not sacrifice the correctness. If applications require all spaces with the maximum weight like the AllMaxRS problem [9], we just need to define the condition as “ \geq ”.

5.3 Discussion

To demonstrate the efficiency and practicality of Algorithm 2, we review the following conceivable approaches that can tight the upper-bound weights maintained by rectangles more than Algorithm 2.

1. An approach that all rectangles r_i maintain *all* the overlapped spaces on r_i .
2. An additional approach of Algorithm 2 that computes the maximum space weight among the common spaces on r_i and r_j when (r_j, r_i) is inserted to $r_i.E$.
3. An additional approach of Algorithm 2 that tries to decrease $s_i.w$ when $s_i.w > s^*.w$.

We show that these approaches do not guarantee the reduction of time complexity, rather, the worst-case time complexity becomes worse than Algorithm 2.

Approach 1. Given a rectangle r_i , we assume that S_i is the set of the overlapped spaces on r_i . Since r_i maintains all the overlapped spaces on r_i , we can compute the tightest $s_i.w$. However, given m' new rectangles overlapping with r_i , we need at least $\mathcal{O}(m' \log |S_i|)$ time in practice¹ to compute the tightest $s_i.w$. Because $|S_i| \geq |r_i.E|$, we may have that $\mathcal{O}(m' \log |S_i|)$ is larger than the time cost of the plane-sweep algorithm, i.e., $\mathcal{O}(|r_i.E| \log |r_i.E|)$. To bound the worst time complexity, we execute Local-Plane-Sweep(\cdot), if $\mathcal{O}(m' \log |S_i|) > \mathcal{O}(|r_i.E| \log |r_i.E|)$ (if we can estimate this situation). Then the worst-case time complexity is the same as Algorithm 1, thus is worse than Algorithm 2. Note that this approach is impractical because we cannot bound the number of spaces maintained by rectangles.

Approach 2. Recall that an optimal way to compute the maximum space weight is the plane-sweep algorithm, thereby this approach is equivalent to the exact s_i computation. That is, this approach does not make sense.

Approach 3. Given a vertex r_i in an aG2, and when $s_i.w > s^*.w$, this approach tries to decrease $s_i.w$. This approach is illustrated

¹In the case where S_i is indexed by an R-tree or a Quad-tree.

Algorithm 5: UpperboundUpdate(r_i)

Input: r_i // a vertex of a given cell.

```

1  $R(r_i) \leftarrow$  the set of vertices that are included in  $N(r_i)$  but have not been executed Plane-Sweep( $\cdot$ )
2  $\tau \leftarrow s_i.w$ 
3 for  $\forall r \in R(r_i)$  do
4   if  $r$  overlaps with  $s_i$  then
5      $\tau \leftarrow \tau + r.w$ 
6     if  $\tau > s^*.w$  then
7        $s_i.w \leftarrow \tau$ 
8       break
9   else
10     $\rho \leftarrow r.w + r_i.w$ 
11    for  $r' \in N(r_i) \setminus \{r\}$  do
12      if  $r$  overlaps with  $r'$  then
13         $\rho \leftarrow \rho + r'.w$ 
14      if  $\tau < \rho$  then
15         $\tau \leftarrow \min(\tau + r.w, \rho)$ 
16        if  $\tau > s^*.w$  then
17           $s_i.w \leftarrow \tau$ 
18          break

```

by Algorithm 5, which may be executed after line 6 of Algorithm 4. Assume an instance when s_i is computed, and let $R(r_i)$ be the set of vertices that are included in $N(r_i)$ after the instance. In other words, s_i has been computed based on $N(r_i) \setminus R(r_i)$. In a nut shell, this approach computes $s_i.w$ by checking whether a given $r \in R(r_i)$ overlaps with s_i (line 4) or the rectangle $r' \in N(r) \setminus \{r\}$ (line 12). Due to the latter case, this approach does not necessarily add $r.w$ to $s_i.w$, which may result in less $s_i.w$ than the original Algorithm 4. This approach however needs an extra $\mathcal{O}(|R(r_i)| |N(r_i)|)$ time for each r_i where $s_i.w > s^*.w$. Recall that Local-Plane-Sweep($N(r_i) \cup \{r_i\}$) takes $\mathcal{O}(|N(r_i)| \log |N(r_i)|)$ time, and we may have that $\mathcal{O}(|R(r_i)| |N(r_i)|) > \mathcal{O}(|N(r_i)| \log |N(r_i)|)$. It would be better to execute Algorithm 5 only in the case where $|R(r_i)| |N(r_i)| < 2|N(r_i)| \log |N(r_i)|$ (since the plane-sweep algorithm needs $2n \log n$ operations). We can therefore see that this approach does not work well if $|R(r_i)|$ is large. Also, this approach increases the worst-case time complexity, which means no guarantee to reduce the time complexity of Algorithm 2. Our experimental results also show that this approach does not guarantee the acceleration of query processing.

From the above discussion, we see that more storage and non-reasonable computational costs are required to tight the upper-bound weights. The upper-bounding cost of Algorithm 2 is reasonable and the worst-case time complexity is better than the above approaches.

6. APPLICATION TO RELATED PROBLEMS

In this section, we address two problems of approximate monitoring MaxRS and monitoring top-k MaxRS. We solve these problems efficiently by employing the branch-and-bound algorithm using aG2 with simple extensions.

6.1 Approximate Monitoring MaxRS

To improve query processing efficiency, some applications require not the exact but approximate results [25]. In this case, it is important to bound the error rate, thus, given a user-tolerance error ϵ ($0 \leq \epsilon < 1$), the objective of this problem is to continuously monitor a space s with the weight $s.w$ that satisfies

$$s.w \geq (1 - \epsilon)s^*.w.$$

Algorithm 2 can deal with this problem by respectively replacing Pruning rules 1 and 2 with Pruning rules 3 and 4, which are shown below.

PRUNING RULE 3. *Given a cell $c_{i,j}$ in the aG2 and the space s monitored by our approximate algorithm, if $(1 - \epsilon)c_{i,j}.w < s.w$, we do not compute the exact $s_{i'}$ of $r_{i'} \in V_{i,j}$.*

PRUNING RULE 4. *Given a cell $c_{i,j}$ in the aG2 and the space s monitored by our approximate algorithm, if $(1 - \epsilon)c_{i,j}.w \geq s.w$, we cannot prune $\text{OverlapComputation}(c_{i,j})$ by Pruning rule 3. Given a vertex $r_{i'} \in V_{i,j}$, if $(1 - \epsilon)s_{i'}.w < s.w$, we do not compute the exact $s_{i'}$.*

We demonstrate that our approximate algorithm (which is the approximate version of Algorithm 2) guarantees the error bound.

THEOREM 1. *Our approximate algorithm always guarantees that $s.w \geq (1 - \epsilon)s^*.w$.*

To prove Theorem 2, we need to introduce the following lemmas.

LEMMA 1. *Assume that we are monitoring s that satisfies $s.w \geq (1 - \epsilon)s^*.w$ before applying Pruning rule 3 to a cell $c_{i,j}$. It is guaranteed that Pruning rule 3 does not lose that $s.w \geq (1 - \epsilon)s^*.w$.*

PROOF. If $c_{i,j}.w < s^*.w$ and $(1 - \epsilon)c_{i,j}.w < s.w$, it is trivial that $(1 - \epsilon)s^*.w \leq s.w$ due to the assumption. On the other hand, if $c_{i,j}.w \geq s^*.w$, we have that $(1 - \epsilon)c_{i,j}.w \geq (1 - \epsilon)s^*.w$. Therefore if $s.w > (1 - \epsilon)c_{i,j}.w$, $s.w > (1 - \epsilon)s^*.w$. \square

LEMMA 2. *Assume that we are monitoring s that satisfies $s.w \geq (1 - \epsilon)s^*.w$ before applying Pruning rule 4 to a vertex $r_{i'}$. It is guaranteed that Pruning rule 4 does not lose that $s.w \geq (1 - \epsilon)s^*.w$.*

PROOF. Essentially the same as the proof of Lemma 1. \square

Now, we are ready to prove Theorem 1.

PROOF. As long as we are monitoring s that satisfies $s.w \geq (1 - \epsilon)s^*.w$, Pruning rules 3 and 4 do not lose the bound, which can be seen from Lemmas 1 and 2. We here assume that we are monitoring s that satisfies $s.w < (1 - \epsilon)s^*.w$. Let c^* be the cell holding s^* , and we have that $s^*.w \leq s^*.w \leq c^*.w$. Therefore, in this case, we definitely cannot prune $\text{OverlapComputation}(c^*)$ and $\text{ExactWeightComputation}(s^*, c^*)$ by Pruning rules 3 and 4, and s is replaced by s^* . This means that s cannot be the result, thus we conclude that Theorem 2 is true from the contradiction. \square

6.2 Monitoring Top-k MaxRS

If the requirement is to monitor not only a single space but multiple spaces with the largest weight, a continuous top-k MaxRS query is a promising solution. This query achieves the requirement while controlling the result size as Definition 4 describes.

We know that Pruning rules 1 and 2 are based on a threshold, and the threshold is $s^*.w$, i.e., the (temporal) top-1 weight. It is intuitively known that the threshold is set as the k th largest weight in continuous top-k MaxRS queries.

Algorithm 6 illustrates the high level algorithm. Although the algorithm for continuous top-k MaxRS queries is essentially the same as Algorithm 2, the main modification is to deal with the set S^* of the k spaces with the maximum weight. We do not show $\text{OverlapComputation}(C')$ and $\text{ExactWeightComputation}(S^*, C')$ because they are also essentially the same as Algorithms 3 and 4, respectively.

7. EXPERIMENTS

Algorithm 6: Branch-and-bound algorithm using aG2 for continuous top-k MaxRS queries

```

1 Execute lines 1–5 in Algorithm 2
2  $C' \leftarrow \{c_{i,j} \mid \exists s \in S^* \text{ is in } c_{i,j}\}$ 
3 if  $C' = \emptyset$  (all spaces in  $S^*$  expire) then
4    $C' \leftarrow \underset{c_{i,j} \in C}{\text{argmax}} c_{i,j}.w$  //  $C$  is the set of cells in aG2
5  $\text{OverlapComputation}(C')$ 
6  $S^* \leftarrow \text{ExactWeightComputation}(S^*, C')$ 
7 for  $\forall c_{i,j} \in C \setminus C'$  do
8   Execute lines 12–15 in Algorithm 2
9 return  $S^*$ 

```

Table 4: Configuration of parameters

Parameter	Values
Window-size, n [$\times 1000$]	100, 250, 500 , 750, 1000

k	1, 5, 10, 15, 20, 25, 30, 35, 40, 45, 50

This section provides our experimental results on the performances of our algorithms. Recall that this is the first work of monitoring MaxRS problem, so there is no existing algorithm that can deal with this problem. Therefore, to show the efficiency of the incremental approach of our algorithms, we use an algorithm with non-incremental approach as comparison. That is, we evaluated naive plane-sweep [12, 18], the algorithm using G2 (Section 4), and the branch-and-bound algorithms using aG2 (Sections 5 and 6). For easy recognition, our algorithms are represented by G2 and aG2. Recall that naive plane-sweep is an optimal in-memory algorithm for computing s^* from scratch, and the algorithm proposed in [8, 9] also uses naive plane-sweep in the case where all objects fit in the main memory. All algorithms were implemented in C++, and all experiments were conducted on a PC with 3.4GHz Intel Core i7 processor and 32GB RAM.

7.1 Setting

Datasets. We used a synthetic dataset and three real datasets. In the synthetic dataset, we generated objects under uniform distribution. The cardinality of this synthetic dataset is 10,000,000, and the range of each coordinate is $[0, 1000000]$. The three real datasets are T-Drive [31], Geolife [34], and Roma², which are the sets of continuously generated GPS data. The objects in the real datasets exist over a very wide range, thus we selected the objects existing around respective main areas. The cardinalities of T-Drive, Geolife, and Roma are 5,037,794, 3,662,876, and 8,368,858, respectively. The objects in the datasets are sorted in order of generation time, and we normalized the range of each coordinate to $[0, 1000000]$. In the above four datasets, the weight of a given object is a real-value randomly chosen from $[0, 1000]$.

Parameters. Table 4 summarizes the parameters used in the experiments and bold values are default values. Note that a given rectangle is a square in the experiments, thus the size of a rectangle is $l \times l$, i.e., 1000×1000 by default.

Evaluation. In Section 7.2, we investigate the impact of Algorithm 5. In Section 7.3, to investigate the performances of the algorithms w.r.t. monitoring MaxRS, we varied three parameters, n , m , and l ,

²<http://crawdad.org/index.html>

Figure 7: Impact of n

Figure 8: Impact of m

Table 5: Computation time [msec]

Algorithm	Synthetic	T-Drive	Geolife	Roma
Algo. 2	0.799	6.547	152.644	55.196
Algo. 5 with cond.	0.796	5.952	202.127	49.245
Algo. 5	0.812	6.229	217.541	54.837

and measured the average computation time to update s^* . We also measured the practical error rate and computation time of aG2 by varying ϵ to investigate the performance of our approximate algorithm in Section 7.4. Let s be the space monitored by our approximate algorithm, and the practical error is defined by $1 - s.w/s^*.w$. Finally, we measured the average computation time to update S^* by varying k in Section 7.5.

7.2 Impact of Algorithm 5

We first study the impact of Algorithm 5 in our default setting. Table 5 shows the result. In Table 5, “Algo. 5 with cond.” is denoted by Algorithm 2 with Algorithm 5 in the case where the upper-bounding cost is less than the plane-sweep cost. We can see that Algorithm 5 provides a trivial impact for all the four datasets and does not outperform Algorithm 2. We observed that $|R(r_i)|$ in Algorithm 5 is large in Geolife, thus Algorithm 5 provides a negative impact. Therefore we do not employ Algorithm 5 since it is not scalable.

7.3 Results on monitoring MaxRS

Impact of n . We study the impact of the number of objects on a sliding-window, and Figure 7 shows the results. All the algorithms need longer computation time as n increases. In terms of naive plane-sweep, this is intuitive since its cost is $O(n \log n)$. It is also intuitive that the increase of the number of overlapped spaces due to the increase of n is likely to lose the chances which avoid `OverlapComputation(.)` and `ExactWeightComputation(.,.)`,

thus our algorithms also need longer computation time. However, we can see that our algorithms are more efficient than naive plane-sweep in the four datasets, as expected. Naive plane-sweep is not scalable, which is shown in the case of large n . Moreover, aG2 scales better than G2 (the computation time is shown in log-scale). aG2 updates the result more than 2 times faster than G2 in the four datasets.

Impact of m . Next, we study the impact of the generation rate, i.e., the number of objects generated at the same time. Although the practical average generation rates of the three real datasets are less than 50 objects (per second), we employ larger generation rates to investigate the scalability of our algorithms. Figure 8 shows the results. Because naive plane-sweep computes s^* from scratch, it is not affected by m basically. The computation time of our algorithms increases as m increases. When m is large, the upper-bound weights maintained by cells and vertices are likely to become large, which results in the same observation as large n . Note that even a case of large m , e.g., $m = 1000$, we can observe that aG2 still updates the result faster than naive plane-sweep.

Impact of l . User-specified rectangle size also has impacts on the performances of continuous MaxRS query processing, because large rectangles tend to overlap with others. Figure 9 shows the results. We can see that aG2 keeps outperforming naive plane-sweep, but the tendencies are different between the datasets. In the uniform distribution, i.e., Figure 9(a), G2 and aG2 are not much affected by l , but in the real datasets, the computation time of our algorithms (and naive plane-sweep) increase as l increases. We observed that the distributions of the real datasets are *skewed*. Therefore many rectangles overlap with each other, then G2 and aG2 are likely to encounter the case that `LocalPlaneSweep(.)` is not avoided.

7.4 Results on monitoring Approximate MaxRS

We evaluated our approximate branch-and-bound algorithm us-

Figure 9: Impact of l

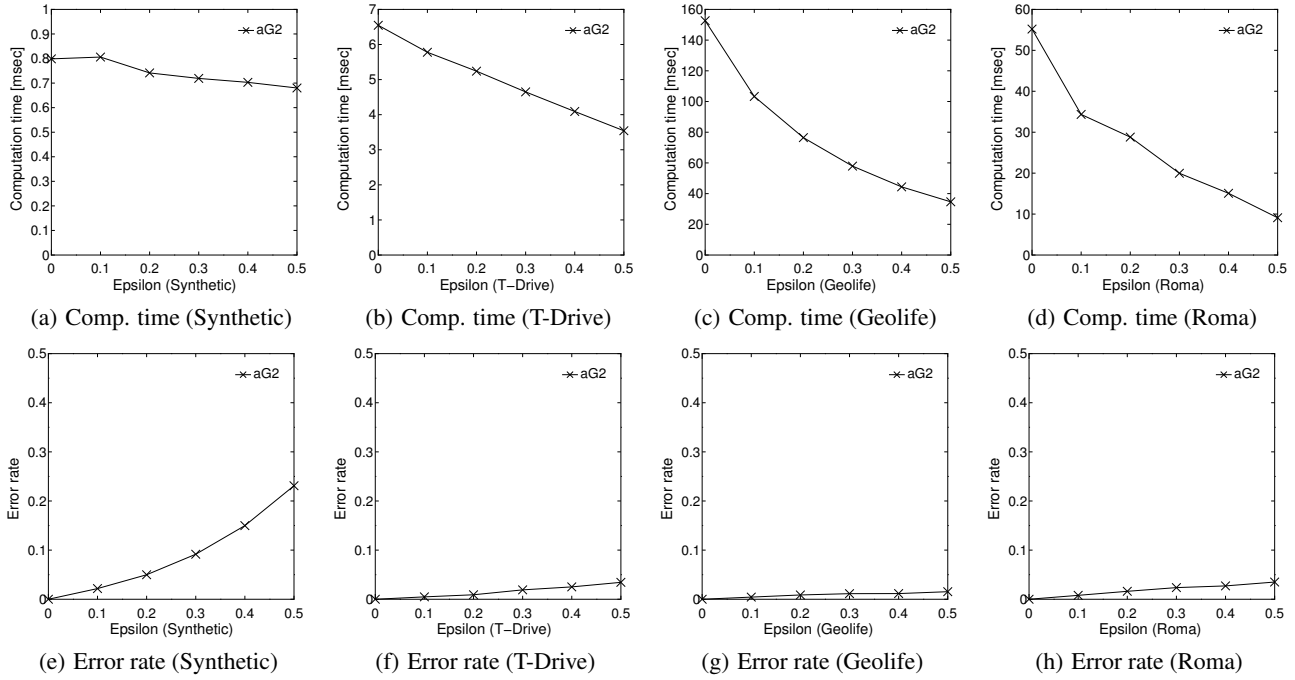

Figure 10: Impact of ϵ

ing aG2 by varying ϵ . Although an approximate algorithm for *one-time computation* of MaxRS queries has been proposed in [25], this algorithm cannot be used for comparison due to three reasons. First, this algorithm is based on randomized sampling, thus the answers returned by this algorithm and our algorithm are different. Second, the answer returned by this algorithm varies every time, which is not suitable as monitoring algorithm. Last, repeating such one-time computation is shown to be inefficient in Section 7.3. We therefore focus on our algorithm, and the experimental results are shown in Figure 10.

From Figures 10(a)–10(d), although its impact is different between the datasets, we can see that the computation time decreases as ϵ increases. This result satisfies the requirement that needs faster computation with an approximate answer. In the synthetic dataset, it seems that the computation time does not decrease so much (Figure 10(a)), but even when $\epsilon = 0$, the computation time is about 0.8 [msec], which is fast enough. From Figures 10(e)–10(h), we can see that as ϵ increases, the practical error also increases but is less than ϵ . The results show that the relationship between the query processing efficiency and the quality of the result is trade-off, but an interesting observation is that the practical error rates in the cases of the real datasets are very small.

7.5 Results on monitoring Top-k MaxRS

To evaluate our branch-and-bound algorithm for continuous top-k MaxRS queries, we conducted an experiment by varying k . We compare our algorithm with naive plane-sweep. Although naive plane-sweep is for one-time computation, this algorithm can deal with top-k MaxRS queries without sacrificing the computation cost. We do not evaluate G2 since its performance is not better than aG2.

Figure 11 shows the results. Again, naive plane-sweep is not affected by k since it scans all rectangles on a sliding-window. As k increases, the computation time of aG2 increases, but we can see that the increase of the computation time of aG2 is slight for all the four datasets. These results confirm that the pruning rules keep efficient and avoid unnecessary computation.

8. CONCLUSION

In this paper, we addressed a novel problem of monitoring MaxRS and its variants, i.e., monitoring approximate MaxRS and top-k MaxRS. In the environments where spatio-temporal objects are generated frequently, monitoring and analysis of objects are often required, and a continuous MaxRS query is useful to support such requirements. Unfortunately, the existing solutions [8, 25] focus on static objects, thus are not efficient in our problem. Motivated

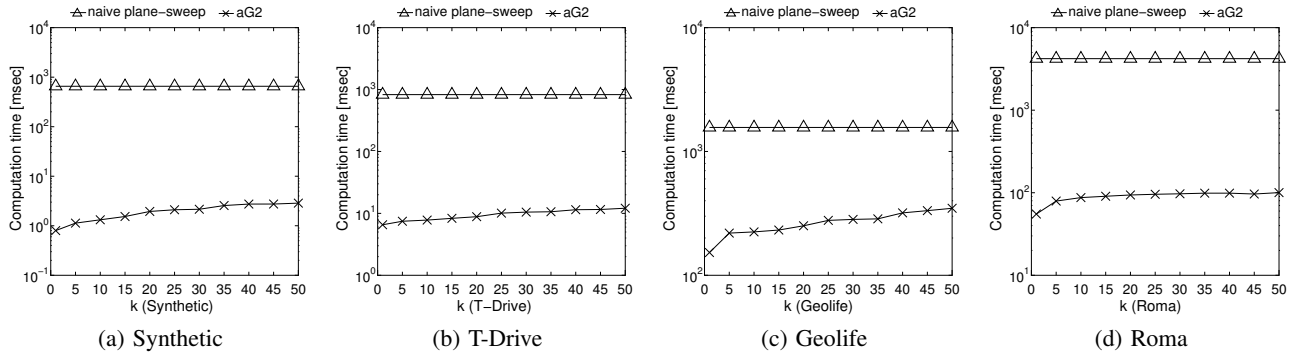

Figure 11: Impact of k

by this, we proposed the first algorithm that can incrementally update the exact result. This algorithm incorporates our index framework G2 (Graph in Grid index) which supports efficient query processing. We extended G2 and proposed aG2 (aggregate G2) and a branch-and-bound algorithm using aG2. The branch-and-bound algorithm accelerates the query processing efficiency. Moreover, we showed that the branch-and-bound algorithm can deal with the monitoring approximate MaxRS and the top- k MaxRS problems with simple modifications. To demonstrate the efficiency of our algorithms, we conducted experiments using synthetic and real datasets. The results show that the branch-and-bound algorithm using aG2 is superior to the one-time computation approach and the algorithm using G2.

As shown (but not theoretically) in Section 5.3, we need extra computation and storage costs to tight the upper-bound weights more. Hence, it is interesting to theoretically explore (or clarify the impossibility of) an approach that can tight the upper-bound the most without sacrificing the computational cost and storage cost. It is also interesting to develop an efficient algorithm that can deal with multiple continuous MaxRS queries at the same time. These are the works that need to be considered in the future.

ABSTRACT

User-generated content on the Web increasingly has a geospatial dimension, opening new opportunities and challenges in location-based services and location-based social networks for mining and analyzing user behaviors and patterns. The applications of such analysis range from recommendation systems to geo-marketing. Motivated by these needs, querying and analyzing spatio-textual data has received a lot of attention over the last years. In this paper, we address the problem of matching point sets based on the spatio-textual objects they contain. This is highly relevant for users associated with geolocated photos and tweets. We formally define this problem as a Spatio-Textual Point-Set Join query, and we introduce its top- k variant. For the efficient treatment of such queries, we extend state-of-the-art algorithms for spatio-textual joins of individual points to the case of point sets. Finally, we extensively evaluate the proposed methods using large scale, real-world datasets from Flickr and Twitter.

Keywords

spatio-textual join, spatio-textual point sets, similarity search

1. INTRODUCTION

Social media platforms such as Twitter, Flickr, Facebook and Foursquare have attracted billions of active users. In the case of Twitter 500 million tweets are exchanged every

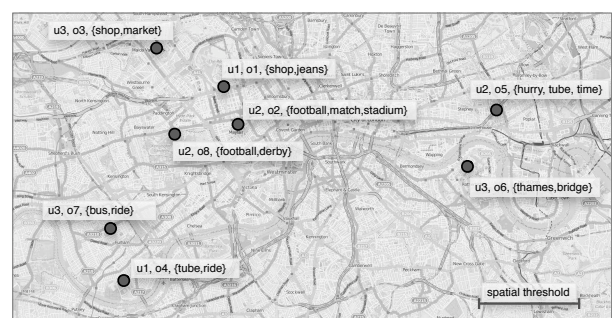

Figure 1: STPSJoin query scenario. Multiple objects are spatially or textually similar, but only users u_1 and u_3 have objects which are mutually similar.

day from 100 million active users. User activities in these platforms generate content that has *textual component*, e.g., status updates, short messages, or tags, and, following the widespread adoption of GPS in mobile devices, a *geospatial component*, e.g., geotagged tweets, photos, and user check-ins. Thus, the actions of users are documented by their messages in social networks and as such generate “traces”, which consist of spatio-textual objects.

Efficient indexing and querying of spatio-textual data has received a lot of attention over the past years, due to the high importance of such content in location-based services, such as nearby search and recommendations. In particular, multiple types of spatio-textual queries have been extensively studied, including boolean range queries, top- k queries, k -nearest neighbor queries, and more recently, spatio-textual similarity joins [11, 7]. Nevertheless, in existing works, *spatio-textual entities are typically treated as isolated observations*. A typical example query is to find nearby restaurants or hotels matching certain criteria.

The work in [7] deals with finding pairs of entities that are both spatially close and textually similar. Example use cases are de-duplicating Points-of-Interest across datasets, or finding matching photos taken at roughly the same location and having similar tags.

Now consider looking for similar users in social networks. Here, a user is characterized by the messages they generate and, if available, respective location information. As such, each message can be considered a spatio-textual object, e.g., a geotagged photo or tweet. With each user being character-

ized by a set of spatio-textual objects, to find similar users, one needs to examine the similarity of these respective sets. Effectively, this characterizes users by what and where they tweet. An example of such a scenario is depicted in Figure 1. To that effect, this work addresses the problem of similarity search for *spatio-textual entities*, with an entity being characterized by a *set of spatio-textual objects*. We introduce the *Spatio-Textual Point-Set Similarity Join* (STPSJoin) query. Given sets of spatio-textual objects, each one belonging to a specific entity, this query seeks pairs of entities that have similar spatio-textual objects.

The STPSJoin can naturally model the search for entities exhibiting similar behavior according to the spatio-textual objects they generate. With social media users posting messages at various locations, the STPSJoin allows us to discover users that exhibit similar “geo-textual” behavior. This holds especially true for location-based social media sites, e.g., Foursquare, where users report on the places they visit. Following the general observation that spatio-textual object sets can be used to define the context of a user, e.g. has family because of frequent toy store visits, the STPSJoin can be used to discover such groups of similar users.

To efficiently process (top- k) STPSJoin, we adapt and extend the state-of-the-art algorithms for processing similarity joins for single points [7]. The proposed algorithms make use of spatio-textual indexes in conjunction with an early termination and a filter-and-refinement strategy to effectively prune the search space, thus reducing the execution time by orders of magnitude. More specifically, the contributions of our work are as follows.

- We formally define the spatio-textual point set similarity join (STPSJoin) query, which extends and generalizes the spatio-textual similarity join for the case of point sets, and its top- k variant.
- We first derive a baseline algorithm for the STPSJoin query by adapting the state-of-the-art PPJ-C algorithm [7] to work for point sets. Then, we propose two optimized algorithms, S-PPJ-B and S-PPJ-F, which apply an early termination and a filter-and-refinement strategy, respectively, to drastically prune the search space. This significantly reduces the number of comparisons required, both in terms of pairs of entities and in terms of individual points for each candidate pair.
- In addition, we present an alternative version of S-PPJ-F, denoted as S-PPJ-D, which relies on an R-tree instead of a grid for the spatial indexing.
- We adapt our methods to efficiently treat the top- k STPSJoin query. We provide a direct adaptation of our best performing algorithm, and extended it in order to allow additional pruning of the search space.
- Finally, we perform an extensive experimental evaluation using three large, real-world datasets. The results of the experimental evaluation demonstrate that the proposed algorithms achieve an order of magnitude and above improvement in terms of execution time when compared to the baseline method.

The remainder of this work is structured as follows. Section 2 reviews related work. The STPSJoin query and its top- k variant are formally introduced in Section 3. The

algorithms for the efficient evaluation of (top- k) STPSJoin queries are presented in Section 4. Section 5 presents an experimental evaluation of the proposed approaches. Finally, Section 6 gives conclusions and directions for future work.

2. RELATED WORK

First, we review recent advances on spatio-textual search, which exploit spatial and textual characteristics in order to efficiently prune the search space while searching for similar objects. Then, we detail the state-of-the-art in similarity joins, in order to establish the basis for our work on point set joins. Finally, we present related literature on user recommendations using location histories.

2.1 Spatio-Textual Search

A large amount of web documents nowadays contain both spatial and textual information, characteristics which are exploited by modern applications to provide enhanced location-based services. Such applications rely on spatio-textual indexing for efficient computation.

Spatio-textual indexes. Current research enables the combination of spatial and textual indexes into hybrid spatio-textual indexes that explicitly support geographically aware search. Established spatial indexes, such as R-trees [22], regular grids, and space-filling curves, are integrated with textual indexes, such as inverted files or signature files. For example, SPIRIT [36] uses regular grids as spatial indexes and inverted files for the indexing of the documents. [43] proposed different approaches to hybrid indexing that employ R*-trees [6] for spatial indexing and inverted files for textual indexing. [12] follows a similar approach, but utilizes space-filling curves for spatial indexing. [15] combines R-trees with signature files, which are stored internally in the nodes of the tree. The IR-tree index [13, 26], leverages inverted files for each node of the tree, in order to keep aggregate information of the textual characteristics of the relevant objects, while [33] uses aR-Trees [30] in combination with inverted files. Spatio-textual search is employed in order to answer a range of queries. An overview of the performance of the most commonly used spatio-textual indexes in such queries can be found in [11].

Spatial group keyword queries. Another type of spatio-textual queries is spatial group keyword queries [40, 41, 9, 29]. These aim at finding groups of spatio-textual objects that collectively satisfy a number of given keywords, while minimizing the collective distances between points in the group and the given query point.

Although the aforementioned queries involve searching for groups of objects, they differ from the problem addressed in this paper. The STPSJoin query is not constrained by an input query point nor a given textual description. In addition, groups of objects are predefined according to the user they are associated with. STPSJoin considers spatial and textual distances of objects across groups, rather than within groups. Finally, STPSJoin deals with the problem of spatio-textual join, which is fundamentally different from range and k NN queries.

2.2 Similarity Joins

Similarity joins seek to identify pairs of objects from given sets that satisfy a predefined similarity threshold.

Set similarity joins. The set similarity join task is computationally challenging; a naive approach requires the consideration of the similarity between every possible pair of objects across sets. Set similarity joins have been extensively studied, especially with respect to textual characteristics, and multiple optimizations have been proposed. [34] uses an inverted index based probing method to reduce the number of potential candidates. [10] observes that the prefixes of potential candidates must satisfy a minimal overlap. The **ALL-PAIRS** algorithm proposed by [5] further optimizes the size of the inverted index. [37] presents **Adapt-Join** and [38] proposes **PPJOIN+** which are the state-of-the-art algorithms for set similarity joins. **PPJOIN+** builds on **ALL-PAIRS** and introduces a *positional filtering principle* which exploits the ordering of tokens, and operates both on the prefix and the suffix of the tokens of objects. **PPJOIN+** is internally used as the final step of our algorithms in order to efficiently compute textual similarity joins. An experimental analysis and evaluation on string similarity joins can be found in [24].

Spatial joins. Data structures and algorithms for spatial joins have been widely studied in the literature. A relevant survey can be found in [23]. Spatial joins have been used in combination both with space partitioning as well as with data partitioning structures. The state of the art algorithm for spatial joins has been proposed in [8]. We utilize this algorithm to prune the search space when searching for spatially relevant users using an R-Tree (see Section 4.1.4).

The problem of spatial joins over point sets has not received much attention. Adelfio et al. [2, 1] focus on similarity search for a collection of spatial point set objects based on the Hausdorff distance. The motivation behind their work is highly relevant to the **STPSJoin** query. However, there are important differences. We consider web objects with spatio-textual characteristics and measure the distance among point sets using a different similarity measure. The Hausdorff distance measures the maximum discrepancy between two point sets, whereas in our work we use a measure inspired by the Jaccard coefficient which focuses on the amount of objects from different point sets that are similar.

Spatio-textual joins. Spatio-textual joins have attracted some attention recently with a specific focus on joins for spatio-textual points. This process is primarily executed for the purpose of duplicate detection. The work in [3] is one of the first examples of spatio-textual join methods. They propose the **SpSJoin** query that follows the MapReduce paradigm for scalable computation of spatio-textual join queries. The spatio-textual join query has been also studied in the form of spatial regions associated with textual descriptions ([27, 28, 20]). Pruning strategies, based on spatial and textual signatures of objects, are employed to filter the number of candidates. [32] presents grid and quad tree based indexes in order to efficiently partition the database either in a local or global fashion. They also explore different dimensions of the problem, including the use of **PPJOIN+** and **All-Pairs** for text similarity joins, as well as single and multi-threaded approaches.

Bouros et al. [7] propose the state of the art spatio-textual join algorithms. Their work builds on top of **PPJ**, a baseline method that extends **PPJOIN+** to account for objects with spatio-textual characteristics and a given spatial distance threshold. The algorithms **PPJ-C** and **PPJ-R** extend **PPJ** by leveraging a grid and an R-Tree based index respectively.

These methods provide the basis for our work; thus, we revisit them in more detail in Section 4.1.1.

Work on spatio-textual joins is highly relevant to our approach. However, the focus is different. To the best of our knowledge, current research in the field has focused on spatio-textual similarity joins among points. On the contrary, our work introduces spatio-textual similarity joins among point sets. Point sets are relevant when objects are grouped with respect to a common characteristic. In this case, the focus is on identifying similarities among groups, rather than single elements. For instance, in the case of web objects, a group consists of objects associated with the same user. In this case, point-set joins identify user similarity instead of object similarity.

2.3 User Recommendation Systems

Matching users based on their location history is one of the main tasks of recommendation engines in location-based social networks [4]. User location histories have been used for identifying local experts, recommending friends, and extracting local communities. It has been revealed by several studies that location information plays a vital role in determining such relationships [14, 16].

Typically, these approaches take into consideration additional information, such as location ratings, semantics of location descriptions and tags, sequence of visit or duration of stay. [25] identifies users with similar traveling patterns based on matching sequences of locations visited by the users. Similar works ([25, 42, 39]) deal with finding users with similar patterns in behavior. [21] study several features to identify users that are similar to a given user. Their methods are based on a logistic regression model. According to their work, a single and in many cases imprecise user location feature (such as city or country) is not effective.

In this paper, we focus on multiple geo-tagged objects for each user, which may provide a better insight into location-based user similarity.

3. PROBLEM DEFINITION

We assume a database \mathcal{D} of spatio-textual objects created by different users U . A spatio-textual object $o \in \mathcal{D}$ is a triple $o = \langle u, loc, doc \rangle$, where $u \in U$ is the user associated with this object, $loc = \langle x, y \rangle$ is a spatial point and doc is a set of keywords. We refer to the user, location and keywords associated with an object o using the notation $o.u$, $o.loc$ and $o.doc$ respectively. In addition, we use D_u to denote the set of objects belonging to user u .

The spatial distance $\delta(o, o')$ between two objects is calculated as the Euclidean distance between their spatial locations. Moreover, the textual similarity $\tau(o, o')$ is measured according to the Jaccard similarity of their keywords:

$$\tau(o, o') = \frac{|o.doc \cap o'.doc|}{|o.doc \cup o'.doc|}.$$

Given a spatial threshold ϵ_{loc} and a textual threshold ϵ_{doc} , we say that two objects $o, o' \in \mathcal{D}$ match if their spatial distance is below ϵ_{loc} and their textual similarity is above ϵ_{doc} . Matching between objects is defined using the predicate μ :

$$\mu(o, o') = \begin{cases} \text{True} & \text{if } \delta(o, o') \leq \epsilon_{loc} \text{ and } \tau(o, o') \geq \epsilon_{doc} \\ \text{False} & \text{otherwise.} \end{cases}$$

For brevity, we overload μ to account for matching an object

with a set of objects $D \subseteq \mathcal{D}$:

$$\mu(o, D) = \begin{cases} \text{True} & \text{if there exists } o' \in D \text{ such that } \mu(o, o') \\ \text{False} & \text{otherwise.} \end{cases}$$

Furthermore, let two spatio-textual point-sets D and D' . Function $M(D, D')$ returns the set of objects in D that match with at least one object in D' :

$$M(D, D') = \{o \in D \text{ such that } \mu(o, D')\}.$$

We then use M to define the similarity of point-sets D and D' . In particular, this is measured as the fraction of the matched points from one set to the other divided by the total number of points in the two sets. Formally:

$$\sigma(D, D') = \frac{|M(D, D')| + |M(D', D)|}{|D| + |D'|}.$$

The employed measure is inspired by the Jaccard similarity, which is not directly applicable since it does not support partial similarity between elements. More elaborate similarity metrics over point sets can be found in [19, 31].

We can now define the *Spatio-Textual Point Set Join* query (STPSJoin). STPSJoin identifies all pairs of users U which are associated with sets of spatio-textual objects that have a match higher than a specified threshold ϵ_u . We assume a total ordering over U (i.e. \prec_U) to avoid returning duplicate pairs. Formally, the STPSJoin query is defined as follows.

DEFINITION 1. Given a database \mathcal{D} of spatio-textual objects belonging to a set of users U , the STPSJoin query is a tuple $Q = \langle \epsilon_{loc}, \epsilon_{doc}, \epsilon_u \rangle$ which returns a set R containing all pairs of users (u, u') such that $u, u' \in U$, $u \prec u'$, and $\sigma(D_u, D_{u'}) \geq \epsilon_u$ with respect to the spatial and textual thresholds ϵ_{loc} and ϵ_{doc} .

An extension of the STPSJoin query in which we seek only the k best pairs of users, in terms of spatial and textual similarity of their objects, is the top- k STPSJoin query. Formally, the top- k STPSJoin query is defined as follows.

DEFINITION 2. Given a database \mathcal{D} of spatio-textual objects belonging to a set of users U , the top- k STPSJoin query is a tuple $Q = \langle \epsilon_{loc}, \epsilon_{doc}, k \rangle$ which returns a set R containing k pairs of users (u, u') such that $u, u' \in U$, $u \prec u'$, and for any pair of users $(v, v') \notin R$ it holds that $\sigma(D_u, D_{u'}) \geq \sigma(D_v, D_{v'})$ for each $(u, u') \in R$ with respect to the spatial and textual thresholds ϵ_{loc} and ϵ_{doc} .

4. ALGORITHMS

This section presents algorithms for the evaluation of the STPSJoin query and the top- k STPSJoin query. First, we present a baseline algorithm, and then we introduce methods that exploit a filter and refine strategy in combination with spatio-textual indexes in order to direct the search. Then, we explain how our methods can be adapted to account for the top- k STPSJoin query.

4.1 Algorithms for STPSJoin

4.1.1 Baseline Approach

Preliminaries. The straightforward method for evaluating an STPSJoin query is to find, for every pair of users, the set of matching objects, and then to check whether the resulting similarity score σ exceeds the specified threshold ϵ_u . Thus,

(a) PPJ-C traversal. (b) PPJ-B traversal.

Figure 2: PPJ-C and PPJ-B grid traversal strategies examples. Objects associated with user u (u') are depicted by squares (diamonds). Matched objects are painted black, objects that do not match are painted white, while objects whose state has not been determined are painted grey. PPJ-B has determined the state of every object in cells 1 to 15, while PPJ-C only the objects until cell 10.

for a pair of users (u, u') , the problem can be cast as a spatio-textual similarity join query, $\text{ST-SJOIN}(D, \epsilon_{loc}, \epsilon_{doc})$, which has been studied in [7]. This query returns all pairs of objects (o, o') in D such that $o, o' \in D$, $\delta(o, o') \leq \epsilon_{loc}$ and $\tau(o, o') \geq \epsilon_{doc}$. Based on this, we can find the objects of u that match with those of u' , and vice versa, and then proceed with computing the score σ for this pair of users.

For this purpose, we adapt the PPJ-C algorithm from [7] for the purposes of ST-SJOINS. PPJ-C uses a grid to partition the space, in order to limit the search to those candidates that can satisfy the spatial predicate of the join. The grid is constructed dynamically at query time, using cells that have an extent in each dimension that equals the spatial distance threshold ϵ_{loc} . The cells are assigned ids in a row-wise order from bottom to top (see Figure 2a).

PPJ-C visits the cells in ascending order of their ids, taking advantage of the spatial filtering, since the objects in each visited cell c need to be joined only with those in c and in the cells adjacent to c . In fact, to avoid duplicates, only the adjacent cells with ids lower than c need to be examined. Thus, for each cell, one self-join operation and at most four non-self join operations need to be performed. These are performed using the PPJ algorithm, that in turn extends the set similarity join algorithm PPJOIN [38] by including an additional check on the spatial distance of two objects.

The S-PPJ-C algorithm. Using PPJ-C as basis, we can derive a baseline algorithm, denoted as S-PPJ-C (Set-PPJ-C), for the STPSJoin query. S-PPJ-C is presented in Algorithm 1. During the construction of the grid, we maintain the following additional information: (a) for each cell c , we maintain the contained objects in separate lists according to the user they belong to; we denote by D_c^u the set of objects of user u that are contained in c ; (b) for every user u , we maintain a list of cells C_u that contain objects belonging to u ; C_u is sorted according to cell ids in ascending order.

The S-PPJ-C algorithm loops through all pairs of users, taking into consideration the total ordering \prec_U of the user set U . For each pair of users (u, u') , S-PPJ-C executes a non-self join version of the PPJ-C algorithm from [7] presented above. The difference with the standard PPJ-C, lies in the fact that in this case pairs with objects from both users are returned. To do so, first the lists C_u and $C_{u'}$ containing the cells for u and u' respectively are gathered. Next, the algorithm iteratively selects from either list the cell c with the lowest id that has not been selected yet. Assume that

Algorithm 1: S-PPJ-C Algorithm

Input: $D, U, \epsilon_{doc}, \epsilon_{loc}, \epsilon_u$
Output: Pairs of matched users R

```

1  $R \leftarrow \emptyset$ 
2  $selectedUsers \leftarrow \emptyset$ 
3  $G \leftarrow createGridIndex(D, U, \epsilon_{loc})$ 
4 foreach  $u_1 \in U$  do
5   foreach  $u_2 \in selectedUsers$  do
6      $r \leftarrow PPJ-C(u_1, u_2, \epsilon_{doc}, \epsilon_{loc})$ 
7      $\sigma \leftarrow \frac{|r|}{|D_{u_1}| + |D_{u_2}|}$ 
8     if  $\sigma \geq \epsilon_u$  then
9        $R.add(\langle u_2, u_1 \rangle)$ 
10     $selectedUsers.add(u_1)$ 
11 return  $R$ 

```

the next selected cell c is from the list of user u . For every cell c' in $C_{u'}$ with $c'.id \geq c.id$, a non-self join version of PPJ is executed with input the spatio-textual point sets D_u^c and $D_{u'}^{c'}$. Since C_u and $C_{u'}$ may both contain the cell c , we avoid the duplicate execution of PPJ for c .

The results of PPJ-C are used to compute the user similarity score σ (line 6-7). Pairs of users that achieve a similarity score above the threshold ϵ_u are collected in the result set.

4.1.2 The S-PPJ-B Algorithm

The drawback of the S-PPJ-C algorithm is that for each pair of users it finds all their matching points and computes the exact value of their similarity score σ before checking whether this exceeds the given threshold. Instead, since we are only interested in finding those pairs with a similarity that exceeds ϵ_u , we can reduce the execution time of the algorithm by terminating the computation for a pair of users as soon as it can be decided that their similarity is below ϵ_u . Following this observation, we derive a more efficient algorithm, denoted as S-PPJ-B (where B stands for bound).

S-PPJ-B operates in the same manner as S-PPJ-C, with the only difference that it replaces the execution of PPJ-C with a modified process, denoted as PPJ-B. PPJ-B leverages the use of an upper bound on the number of unmatched objects for a pair of users to effectively prune the search on the spatial grid. More specifically, the intuition behind PPJ-B is the following. While examining two users, PPJ-B leverages the user similarity threshold ϵ_u and the number of objects belonging to each user in order to compute an upper bound on the number of unmatched objects between the two users, above which the user similarity cannot exceed ϵ_u . In the following, we first derive this upper bound, and then we explain the process followed by PPJ-B in order to allow for early termination during the examination of two users.

For a pair of users (u, u') , let $\beta_{u,u'}$ denote the number of objects from user u and user u' that do not match with the other user, i.e.:

$$\beta_{u,u'} = |D_u| + |D_{u'}| - |M(D_u, D_{u'})| - |M(D_{u'}, D_u)|$$

An upper bound for $\beta_{u,u'}$ is derived as follows.

LEMMA 1. *For a pair of users (u, u') , if $\beta_{u,u'} > (1 - \epsilon_u) \cdot (|D_u| + |D_{u'}|)$ then $\sigma(D_u, D_{u'}) < \epsilon_u$.*

PROOF. The proof is derived from the definition of the

Figure 3: Spatio-textual structure for S-PPJ-F and S-PPJ-D.

similarity score between two users, as follows:

$$\begin{aligned} \sigma(D_u, D_{u'}) \geq \epsilon_u &\Rightarrow \frac{|M(D_u, D_{u'})| + |M(D_{u'}, D_u)|}{|D_u| + |D_{u'}|} \geq \epsilon_u \Rightarrow \\ \frac{|D_u| + |D_{u'}| - \beta_{u,u'}}{|D_u| + |D_{u'}|} &\geq \epsilon_u \Rightarrow 1 - \frac{\beta_{u,u'}}{|D_u| + |D_{u'}|} \geq \epsilon_u \Rightarrow \\ \beta_{u,u'} &\leq (1 - \epsilon_u) \cdot (|D_u| + |D_{u'}|) \end{aligned}$$

□

Upon traversing a cell c , PPJ-C checks for potential matches in cells with ids lower than $c.id$. Therefore, we cannot be certain that objects that have not been matched so far will also not match with objects in cells with higher ids (i.e. in the next cell or row). Therefore, the bound may be used within PPJ-C, but only with respect to the objects discovered from the beginning of the grid until the previous row. The objects that were traversed in the current row have to be excluded from calculation.

To that end, PPJ-B devises a different grid traversal strategy that allows the pruning mechanism to utilize every object appearing in cells traversed when the bound evaluation is executed. Specifically, this strategy traverses the rows from bottom to top (considering the id of the bottom row as 1), and depending on whether the id of a row is odd or even, different treatment is followed. If a cell $c_{i,j}$ belongs to a row with odd id, i.e. j is odd, then the objects contained in it are matched with objects from all surrounding cells, except the cell directly on the right, i.e. $c_{i+1,j}$. Matching is done by executing PPJoin. Otherwise, if the cell belongs to an even row, then we match its objects only with objects from the other user from the cell that is directly on the left, i.e. $c_{i-1,j}$. This process is illustrated in Figure 2b.

Following this traversal strategy, PPJ-B allows for early termination using the bound β , while still maintaining the property of PPJ-C to avoid duplicate examination of the same pair of cells. Indeed, when PPJ-B traverses the last cell of an odd row, it has considered every potential match for any object it has encountered up to that point. Thus, it checks whether the number of objects that have not been matched exceeds the calculated bound β . If so, the search stops, since it is impossible to result in a user similarity score that exceeds ϵ_u . Note that, in practice, since the grid may be rather sparse, some rows may be empty. In that case, when the next visited cell belongs to a row that is not directly above the previous one, the same check can be performed, even if the last examined row was even, since previously encountered objects cannot have any future matches.

4.1.3 The S-PPJ-F Algorithm

The S-PPJ-B algorithm presented above exploits an upper bound on the number of unmatched objects between two

users in order to allow for early termination when comparing each pair of users. In the following, we present the S-PPJ-F algorithm that further increases efficiency by following a filter and refine strategy that concentrates the search on those pairs of users that are promising candidates, while pruning others that can not exceed the similarity threshold ϵ_u .

Algorithm 2: *S-PPJ-F* Algorithm

Input: $D, U, \epsilon_{doc}, \epsilon_{loc}, \epsilon_u$
Output: Pairs of matched users R

```

1  $R \leftarrow \emptyset$ 
2  $G \leftarrow \text{initialiseSTGridIndex}(D, \epsilon_{loc})$ 
3 foreach  $u \in U$  do
4   foreach  $c \in C_u$  do
5      $T \leftarrow \text{calculateTokens}(u, c)$ 
6     foreach  $c' \in G.\text{getRelevantCells}(c)$  do
7       foreach  $t \in T$  do
8         foreach  $u' \in G.\text{getTokenUsers}(c', t)$  do
9            $M_{u'}^u.\text{add}(c), M_{u'}^u.\text{add}(c')$ 
10     $G.\text{addUser}(u)$ 
11    foreach  $u' \in M.\text{keys}()$  do
12       $m \leftarrow \sum_{c \in M_{u'}^u} |D_u^c| + \sum_{c' \in M_{u'}^{u'}} |D_{u'}^{c'}|$ 
13       $\bar{\sigma} \leftarrow \frac{m}{|D_u| + |D_{u'}|}$
